

The other thing you can do to help alleviate things a bit is to increase the dough absorption which will make for a softer, more easily rounded dough, if this will alter the style of pizza you're making is something that I cannot answer.

[Re: Repetative strain in hands from rounding 1981](#)

The method described here, cutting a piece of dough from the large fermented dough mass, and immediately flouring and sheeting it (NOT ROUNDING IT) is the same process commonly used by pizzerias back in the late 40's and through the 50's. It died out in the 60's when we began looking for a more effective way to manage the dough as this method had two major flaws. 1) It gave pizzas that were somewhat inconsistent as the dough continued to ferment and change throughout the day. 2) It limited the number of pizzas which could be sold without fear of having to toss out masses of unused dough. This procedure was ultimately replaced by a variation of the cold fermented dough ball method of dough management we see widely used in pizzerias today. It was also this process that resulted in high protein flour becoming known as "pizza flour" as you needed all that protein content to give the dough the necessary fermentation tolerance to hold up to all those hours of fermentation at room temperature. A typical dough formula from those bygone years will look something like this:

Flour: All Trumps 100%

Salt: 2.5%

Yeast: (compressed, as we didn't have IDY at that time) 0.5%

Sugar: 2%

Water: 55%

The dough was started approximately 6 to 8-hours prior to use and used throughout the day/evening or until it was gone. Unused dough was tossed out. A piece of dough was grabbed and cut from the bulk dough piece, it was floured and sheeted to thickness and trimmed to size. Trim scrap might have been saved but was usually just tossed out. The dough sheet was commonly docked, then dressed and baked in a deck oven at 500 to 525F.

[Re: Pizza with last minute balling ?1982](#)

Carl;

Are you saying that you don't have 4-square feet (2 X 2) to spare in your kitchen? That's all the space required by an AM-Round O Matic. Sure rounders cost some money but then so does a life long disability not to mention the associated medical costs. I don't know how you're presently rounding your dough balls but if you go to my web site at <www.doughdoctor.com> and peruse through my videos you will be able to see how I round my dough balls. I've been teaching this method to operators for years and it really works well, fast and with a lot less strain (absolutely nothing on the fingers).

[Re: Repetative strain in hands from rounding 1983](#)

Without knowing your dough formula and management procedure I can't say too much but as a rule, by adjusting the IDY to about 0.45% and increasing the total dough absorption to around 65% (assuming you are using a flour with 12 to 12.8% protein content) you should be able to effectively manage your dough straight out of the cooler after 36 to 48-hours cold fermentation time, again assuming a finished dough temperature of 70 to 75F and balling the dough immediately after mixing for cold fermentation and cross-stacking/down-stacking after at least 2-hours (another assumption). A lot of assumptions I know, but that's the best I've got to go on for

now.

[**Re: Tweaks for using cold dough?1984**](#)

Here's another idea to try,

Remove the dough balls from the fridge, make sure they are lightly oiled to prevent crusting, partially flatten the dough balls to about 1.5-inches thick, place the flattened (puck shape) dough balls onto a cookie sheet and place in a warm location (on top of the stove?), turn the dough pieces over after 20-minutes and allow to go for another 20-minutes, then begin opening them into skins by your preferred manner. This is similar to how we force the dough in a commercial pizzeria setting. If you don't pre-flatten the dough balls into "pucks" they are very difficult to warm properly as only the outside gets warmed while the middle is still cold.

[**Re: Timing my dough balls1985**](#)

Actually, any potable water with a neutral or very near neutral pH should work just fine. Remember, sourdoughs were born in the presence of well water/natural spring water. With today's municipal water treatment facilities seemingly all over the board with water quality (well documented fact) as a general rule I might suggest that bottled spring water/mineral water be used when working with sourdough systems unless you know that your doughs will perform OK with your tap water.

[**Re: Better / best water to use?1986**](#)

Parchment paper will not help in the least, the idea is to have the pizza supported/raised up off of the bottom of the box to allow steam/moisture to escape (that's what makes the bottom soggy). Cutting a delivered pizza in front of the customer? I can see it for a carry out pizza but not for a delivery pizza.

[**Re: Keeping pizza hot and not soggy when transporting to customers1987**](#)

To answer your first question it has to do with two things, one is realignment of the gluten bonds and the second has to do with exposing the gluten bonds to oxygen which restrengthens the gluten. We do this on a commercial basis using 2,800 pound dough mixers where the dough is mixed until it becomes almost too soft to handle, then the mixer door is opened to allow air/oxygen to replace the carbon dioxide inside the mixing chamber and the dough is then mixed at slow speed to expose it to the air, much like what you do when re-rounding the dough balls, the dough is then finished with a short mix at high speed and discharged for processing. This is done for either of two reasons, it can be done to address an over fermented dough resulting from a delay in production or it can be done to allow for the addition of more water (higher absorption) to the dough.

To answer your second question, this is a step commonly taken when working with high absorption doughs, the rest period in the mixing bowl acts like an autolyse period allowing time for the flour to better absorb the water. If done correctly, there is good scientific evidence that the dough mixing period prior to the rest period opens the gluten structure allowing it to better absorb water which allows the dough to carry even greater amounts of water without becoming excessively soft and unmanageable. In bakery terms this process is referred to as the "fatigue dough mixing method". By this method the dough is mixed to just short of full development with the greater dough absorption, it is then tumbled in the mixer at low speed with the mixing bowl partially open to allow for the entry of air, this is done for several minutes during which the dough becomes noticeably tighter, it is then mixed at high speed for a very short time just to give it the desired

extensibility and discharged for processing. This procedure really isn't suited for pizza production though as pizza doughs are NOT mixed to full development in the manner as bread doughs are.

[**Re: re-ball^{ing} dough before use?1988**](#)

If you're machine mixing and you are using all very cold water it's best to add the IDY to the dough after about a minute of mixing time. If you are hand mixing you are better off suspending the IDY in a small amount of 95F/35C water, you can then add it to the cold water without any issues.

[**Re: Ice cubes in dough hydration and adding oil1989**](#)

All the time.

[**Re: Wooden pizza peel in WFO?1990**](#)

Factors affecting baking time:

Dough formulation.

Dough fermentation.

Oven type and design.

How the oven is fired (gas, electric, wood, coal)

Baking temperature.

Baking platform and color.

Dough weight/thickness.

Type of pizza.

Application of pizza (dine in v/s DELCO)

Type and amount of toppings.

I probably missed a couple but I think those are the high points.

[**Re: Dough Formulation and bake time1991**](#)

The main "good thing" in the water used for making dough is calcium. If you use "0" water and add 0.25% (total flour basis) calcium sulfate you will have about the best you can hope for in a bread or pizza dough.

[**Re: Better / best water to use?1992**](#)

Here are some suggestions for a better DELCO pizza.

1) Bake the pizzas as long as possible.

2) Bake your pizzas in an air impingement oven for a drier top.

3) Minimize vegetable toppings.

4) Do not cut the pizza.

5) Allow pizza to steam off for a minute prior to boxing.

6) Use a ripple sheet or Dri-Pie Mat under the pizza in the box.

7) Make sure steam vents in boxes are opened.

That's about the best you can do.

[**Re: Keeping pizza hot and not soggy when transporting to customers1993**](#)

Hard tap water is going to be the best to use. Don't worry about the hardness, the harder the better as far as the dough is concerned. If taste is an issue for you use an activated carbon filter. R.O water is probably the worst water to use in a dough with softened water running a close second. The dissolved minerals actually strengthen the dough (especially the calcium).

[**Re: Better / best water to use?1994**](#)

You get a higher BTU exchange when using ice as opposed to ice water...big

difference. When using ice it is not recommended that "ice cubes" be used as they do not melt very well, instead, use shaved ice or flake ice. Very seldom do we ever need to add ice to a dough to achieve the desired finished dough temperature unless we're making some type of a frozen dough or we have a very hot mixing room to contend with. For most doughs with a targeted finished dough temperature in the 70 to 85F range water temperature in the 55 to 65F range will be sufficient.

[**Re: Ice cubes in dough hydration and adding oil 1995**](#)

PA;

No offense taken. :)

[**Re: In need of guidance 1996**](#)

Mix the dough until all of the ice has melted, then add the oil gradually over 60-seconds or so.

[**Re: Ice cubes in dough hydration and adding oil 1997**](#)

There is no need to "bloom" IDY when hand mixing, just suspend it in a small amount of plain water at 95F (temperature is critical with IDY).

No need to "eye ball" the yeast, just put it into a known quantity of 95F water, suspend it and divide the water. for example, if you need 1-gram of IDY you can weigh 2-grams into the water and use only half of the water. If you want 0.5-gram just divide the water by four. This is a pretty common practice where small amounts of an ingredient are needed, it sure beats the "guess and by gosh" method.

[**Re: In need of guidance 1998**](#)

If you are using a mechanical dough mixer it will take care of distributing the yeast throughout the dough just fine, if you are hand mixing it will be necessary to suspend the yeast in all or a portion of the water (compressed yeast). Process is the same if you ferment the dough balls at room temperature, just don't put them in the fridge and adjust the finished dough temperature to 70F/21.1C to 75F/23.8C.

[**Re: In need of guidance 1999**](#)

If your mixer has a common "J" hook the dough most likely just grabbed onto the hook and went for a ride with it around the bowl without receiving much, if any, mixing input/action. In a case like this if the dough temperature was much under 80F/26.6C with your yeast level, the dough was under significantly under mixed (making it sticky to handle with poor shape retention) and quite likely it was under fermented too resulting in a tight, bucky (elastic) dough condition when you were trying to form the skins.

You might try this:

Mix your dough as you are, check the finished dough temperature, you are looking for 80F/26.6 to 85F/29.4C (adjust the water temperature to give you this finished (mixed) dough temperature. Immediately scale and ball the dough, place into individual plastic bread type bags (twist the open end into a pony tail and tuck it under the dough ball as you place it into the fridge). Note: Lightly oil your hands to make handling the sticky dough easier, make sure dough balls are lightly oiled when placing into bags. Allow the dough to cold ferment in the fridge for 24 to 48-hours, remove from fridge and allow to warm AT room temperature for about 1-hour, turn dough ball out of the bag onto a floured surface, flour the dough ball and open into a skin. It should handle and open much easier thanks to bio-chemical gluten development.

To answer your question about "dough management": Dough management is

everything that you do to the dough from the time it is mixed until you open it into a skin.

[Re: In need of guidance](#)**2000**

You say you allowed the dough to rise for 6-hours prior to baking, when did you open the dough ball into a skin, before or after that 6-hours at room temperature (whatever temperature that might be).

[Re: I haven't been able to duplicate my bubble crust after succeeding once.](#)**181**

My fear is that you are jumping back and forth between sourdough and conventional pizza and bread type doughs, is this a correct observation?

[Re: Dough science - minutes after cold ferment but before baking?](#)**182**

A malted bread type flour will certainly work a lot better for you right now. Read the ingredient label on the flour bag for contains: malted barley flour, or it may just say "enzymes" (which would be amylase enzymes which act as the malted barley flour does). You can also see if you can find some diastatic malt powder. You will want to have a diastatic malt powder with a 20 degree Lintner Value. This will need to be added to the dough as an ingredient at 0.25%. If you get a diastatic malt with a higher Lintner Value divide the value by 20 and then divide 0.25% by the same number to find the amount to add. For example, if you get a 60 degree Lintner Value malt; 60 divided by 20 = 3 so you will now divide 0.25% by 3 = 0.0833% (this is the amount of the 60-L malt that you will need to add).

[Re: Getting crust to brown without being to overcooked and hard.](#)**183**

Without more details it's hard to say what the issue might be but just for grins, try using only 10% of your starter the next time. All starters are different and because of that the amount used will very too.

[Re: help diagnose dough issues using SD starter](#)**184**

In addition to what Yael has said, with reference to the yeast, within the yeast that you add, some of the cells are budded, and some are not, those that are budded, with sufficient fermentation time, the buds will grow and develop into "daughter" cells however they themselves will not bud (reproduce) which partially explains why fermentation will tend to speed up to a point in the fermentation process and then level off with fermentation continuing at a steady rate until the process is interrupted by alcohol content, nutrient depletion, or temperature.

[Re: I haven't been able to duplicate my bubble crust after succeeding once.](#)**185**

At the levels we're talking about using here it won't make a difference which one you use, BUT if you use butter, use it at room temperature and you don't need to use the delayed oil addition mixing method, you can just add it right on top of the flour.

[Re: NY Style in my Wood Fired Oven](#)**186**

Additionally, yeast doesn't replicate in a dough, it just feeds and generates by-products of fermentation.

[Re: I haven't been able to duplicate my bubble crust after succeeding once.](#)**187**

It might. Try 1% powdered garlic (not garlic salt).

[Re: Pizza Slap Practice Dough](#)**188**

Just don't freeze the dough for more than about two weeks, three on the outside,

and anticipate a long time for the dough to become active again after the freezing process. This is one reason why frozen dough typically has a higher yeast level.

[Re: Flat dough from sour dough starter in lieu of IDY](#) **189**

A number of years ago I spoke with a major pizza box store franchise owner about a similar question, his response at the time was was that one doesn't really begin to make money (as an investment) until he/she owns at least three to five stores. If I remember correctly, at the time he owned about 12 stores and was doing quite well. The old adage of "It takes money to make money", has a familiar ring in this case.

Owning an independently owned/operated store can have its advantages too, but it takes a lot of leg work (blood, swear and tears) to get it off the ground, and if you're successful at that you will then be faced with getting good help, let me repeat that in another way, getting good help today is the number one biggest challenge an independent store has today. It is also the number one stifle to independent store growth/expansion. But this is the price we pay to be an independent store owner/operator. I might also add, if you are a micro-manager or feel that you just cannot get away from the shop for any reason, abandon any idea of being an independent, you're doomed to failure, instead invest your money in the stock market, you'll be a lot happier and more successful.

[Re: Franchise vs. Independent, raising the money to open](#) **190**

We did some work along those lines back in the 1970's but the problem that we had was that we couldn't get consistent results so the amount of mix time reduction and dough extensibility were all over the board. To the best of my knowledge this work was done prior to the advent of "dead yeast" for use as a reducing agent. What has to be done is to heat a yeast suspension to the the thermal death point (140F) to inactivate the yeast without denaturing the glutathione which will now be the active ingredient. Remember, the amount of glutathione used in a dough to achieve desired results is measured in PPM (parts per million), so it doesn't take much to cross the line between something that works well in a dough and something that's disastrous for a dough.

[Re: ADY to prove or not](#) **191**

No correction needed, Peter "nailed it" ^^^

[Re: Cold Fermentation advice](#) **192**

If you will email me at <thedoughdoctor@hotmail.com> I'll be glad to send you a copy of my Dough Management Procedure which contains all of the elements necessary for effective management of your dough through the cold fermentation process.

[Re: Cold Fermentation advice](#) **193**

Just a tip: One cannot accurately state the amount of starter needed without first knowing the strength of the starter in question. Commercial yeast (IDY, ADY and CY) are standardized in strength and very uniform/consistent when fresh which is why we can, with good accuracy, predict the amount of yeast needed for a specific fermentation scenario. The same is not true for sourdough starters since they are "natural" and vary accordingly. To recommend an amount of IDY to use we will need to know the specifics (including all times and temperatures) pertinent to your dough/dough management procedure.

[Re: Flat dough from sour dough starter in lieu of IDY](#) **194**

Yael is correct, only the flour, remember....we change only one thing at a time. The list that I provided is a list of options that might help by strengthening the dough, thus allowing it to better support the weight of the toppings without collapse.

[**Re: How to achieve a better spring/sponge in the pizza**](#) **195**

Agreed, most sourdough starters do not play well in cold temps, plus if you used your starter at the same level as IDY you were VERY low on leavening. You should have been using it at something in the 5 to 15% range depending upon the strength and acidity of your starter.

[**Re: Flat dough from sour dough starter in lieu of IDY**](#) **196**

I would take the sourdough starter out for now, just use IDY (0.25%) for the leavening. Once you get something that you like you can then change over to your starter at different levels (5%; and 10%) to start with and adjust accordingly from there.

[**Re: Issues with Elasticity**](#) **197**

This may come under the Federal Food Protection Act, if it does, the person committing the crime will be Federally prosecuted and if found guilty will be sentenced to a mandatory 20-years in a Federal prison. This is the reason why we see so little of this anymore. It used to be a lot more prevalent.

[**Re: Another reason to make your own dough...**](#) **198**

Issues relating to excessive elasticity are almost always related to insufficient fermentation in one way or another.

[**Re: Issues with Elasticity**](#) **199**

While I've not done it, your question is interesting. You might try making a dough as follows:

Flour: All Trumps or the highest protein baking flour available (14% to 14+% protein content) 100%

Salt: 3%

PZ-44: 2% (variable)

Oil: 4%

Water: 58% (variable) 70F.

Mix the dough until it has the desired extensibility, scale and ball.

Begin practicing with one dough ball right away, lightly oil and wrap the others in plastic and store in the refrigerator. At some point the first dough ball will become too extensible to play with, at that point re-ball it and place it in the refrigerator and remove one of the other dough balls, keep repeating until fun time is over.

Let us know if this works for you.

[**Re: Pizza Slap Practice Dough**](#) **200**

With a large dough box and just a couple dough balls it's like putting those two dough balls into a gymnasium and expecting them not to dry out. We just recently had some discussion on this very topic and how to address it.

[**Re: Dough tray**](#) **201**

The picture I was referring to appears to be a pan pizza but the outside of the pan appears to be bright and shiny, which would raise concern with bake color especially in an air impingement oven.

What do you have for a top and bottom finger profile?

[Re: Dough not rising and too white 202](#)

Your dough might also be a bit over absorbed, if additional oil and a shorter fermentation time don't work reduce the dough absorption by 5% to see how that works, remember dough absorption is ALWAYS variable.

[Re: Dough sticks to proofing container, deflates while removing? 203](#)

Raj1;

Is that a picture (2nd from last) of your deep-dish pizza still in the pan in which it was baked? That pan looks to be bright silver in color? Please confirm and show pictures of the OUTSIDE of the pan.

Thanks,

[Re: Dough not rising and too white 204](#)

At your present 0.25% IDY level you will be just fine even if you increase the salt to 2.2%. If you want to go more than that increase the IDY to 0.3 to 0.375% and you can go as high as 3% salt.

[Re: Want to add more salt 205](#)

I cannot answer that question as it is dependent upon a number of factors relating to the strength of your dough, about which I know nothing. You'll have to try them to determine if they will hold up or not. If they don't hold up you can make something else from the dough like garlic knots or bread sticks or you can add them back into fresh/new dough at up to 15% of the total new dough weight.

[Re: Dough not rising and too white 206](#)

That one will certainly work for you. I always recommend the dial/stem type since they are so much lower in cost and are easily re-calibrated.

[Re: Dough a little sticky, maybe not rising enough? 207](#)

Just get yourself a dial/stem type thermometer with a hex nut under the dial. This nut is used to calibrate the thermometer. To calibrate a thermometer: Use a low cost oral thermometer and adjust the water temperature in a glass so the temperature reads on the oral thermometer, then place the stem/dial type thermometer in the glass of water and adjust the temperature by holding the head and turning the nut until the temperature reads the same as the oral thermometer, your thermometer is now calibrated.

[Re: Dough a little sticky, maybe not rising enough? 208](#)

Don't worry too much about the flour temperature at this time, instead just concentrate on the finished dough temperature which is typically in the 75 to 80F range. If you are mixing by machine you can use this formula for calculating the dough water temperature: 145 minus flour temperature = desired water temperature for a finished dough temperature of about 80F. If you are mixing your dough by hand you will need to experiment with the water temperature.

[Re: Dough a little sticky, maybe not rising enough? 209](#)

After the cold fermentation of the dough balls and you press the dough into the pans, you will need to experiment with how long you allow the dough to proof/rise in the pan before placing them back into the walk-in cooler. My advice is to take a few at 15-minute intervals: 15, 30, 45 and 60-minutes. Cover them or better yet, place in a wire tree rack which is covered with a large plastic bag. After about

3-hours begin testing by removing pans of proofed dough beginning with 15-minutes and going all the way to the 60-minute proofer dough. As you remove the proofed dough immediately dress and bake, then evaluate and decide which proofing time provided you with the best finished crust characteristics. Send us some pictures of the whole pizzas and also of each pizza cut in half so we can see the thickness as well as the crumb structure.

[**Re: Dough not rising and too white**](#)**210**

Here is a good basic dough formula that should work well for you.

Flour: (strong bread type flour with at least 12% protein content, higher protein is even better) 100%

Salt: 2%

Sugar: (variable/optional) 2%

Yeast: (CY: 1%) or (ADY: 0.5%) or (IDY: 0.375%)

Water: (variable) 62%

Oil: 2%

Use delayed oil addition mixing method.

Target finished dough temperature: 75 to 80F

Procedure:

Mix.

Scale and ball within 20-minutes.

Place in plastic dough boxes and oil top of each dough ball.

Cross-stack in the cooler until INTERNAL dough ball temperature reaches 50F.

Down-stack.

Cold ferment minimum of 24-hours, 48-hours is better.

Remove from cooler and allow the set AT room temperature until the INTERNAL dough ball temperature reaches 50F.

Begin opening dough balls into skins.

[**Re: NY Style in my Wood Fired Oven**](#)**211**

The dough looks fine to me, but you're going to need to do some work on the dough formula, for example (1/3 hot and 2/3 cold) how hot? How cold? Remember, it's not the hot and cold that matters, it's the actual temperature of the water that counts. Also, there was no mention of finished dough temperature, I always say that you cannot have effective dough management without effective temperature control. Assuming room temperature fermentation after balling so a total of 24-hours room temperature fermentation.

[**Re: Dough a little sticky, maybe not rising enough?**](#)**212**

Raj1;

With compressed yeast you should be OK using 1%, I don't think 0.5% will be sufficient.

[**Re: Dough not rising and too white**](#)**213**

Correct me if I'm wrong, but that looks like a cookie sheet? What does the bottom look like? If you are trying to achieve a hearth bake that's not the best option, a baking steel or stone will serve you much better.

I second the nomination to upgrade to a better "baking surface" ^^^

[**Re: Writing this intro while my dough gets up to room temperature**](#)**214**

Raj1;

I agree with Yael that 24-hours at room temperature with your dough formula is

going to be too much fermentation and result in a low pH condition of the dough which will impede crust color development. Can you follow my Dough Management Procedure and target a finished dough temperature of 75 to 80F, go directly from the mixer to the bench for scaling and balling, then box the dough balls and oil the top of each ball and then into the cooler for cross-stacking (all within 20-minutes of removing the dough from the mixer), allow the dough balls to remain cross-stacked until the INTERNAL dough ball temperature reaches 50F/10C and then down-stack or cover the boxes. Allow to CF for 24 to 48-hours, remove from cooler (keep boxes covered) until INTERNAL dough ball temperature reaches 50F/10C, then begin fitting the dough to the pan(s) and allow to final proof for about an hour or whatever time is needed to give the desired finished crust height/thickness. Baking deep dish pizzas at too high of a temperature usually results in not getting the internal crumb structure properly baked while in many cases scorching the toppings at the same time.

[Re: Dough not rising and too white](#)**215**

That's a lot of (ADY?) even more if it's IDY. The amount shown calculates out at 1.2% while a more typical level is 0.5 to 0.75% if it's ADY or 0.4 to 0.6% for IDY for pan style pizza. I should also add that if it's ADY it should really be hydrated and activated separately in a small container with about five times its weight of warm (100F) water. If the yeast is IDY you can just add it dry right to the flour. What is the finished dough temperature? Ideally you should be looking for something in the 80 to 85F range.

[Re: Pizza Hut pan pizza dough rising too much](#)**216**

Send us some pics of that aluminum "surface" (not quite sure what you mean by that), so we can see what you have and possibly make some recommendations to help you achieve your pizza making goals.

Welcome!

[Re: Writing this intro while my dough gets up to room temperature](#)**217**

I looked them up for you, they are called wooden bagel proofing boards/Bakedco.com/\$8.75 each./size 18 X 26

[Re: Trays for rack](#)**218**

They look like bagel boards, used to be made out of wood but now made from a plastic like material. Look for "bagel boards".

[Re: Trays for rack](#)**219**

Once you have an active starter it is typically maintained at about the consistency of heavy cream. It's a starter, not a sponge or biga. Depending upon the characteristics of the starter, you will probably use it at something between 5 and 15% in making your pizza dough (be sure to take the water content of the starter into account when calculating the total dough absorption).

[Re: Sour dough starter experience](#)**220**

The amount of ascorbic acid added to IDY is VERY small (measured in ppm (parts per million). Its purpose is to compensate for the small amount of glutathione released from the yeast during the drying process thus giving the IDY a performance profile more like that of CY. To get the effects that were mentioned you would need to add something between 75 and 100 times as much ascorbic acid AND it would need to be a coated/encapsulated form of ascorbic acid.
No truth to what you heard.

[Re: Does ascorbic acid make tougher dough?](#)**221**

A picture would help immensely, but lacking that it might be insufficient IDY. Are you weighing the IDY?

[Re: Puffy Crust but has raw dough](#)**222**

No problem as long as you dispose of it at the end of each day.

[Re: Flavored and Infused Oils](#)**223**

With everything that has been already said, spend some time visiting with your local codes department to make sure whatever you end up doing meets with their approval, it will in the end, no matter what, so make it easy on yourself and do it the way they want it right from the start. Visiting another local store to see what they have may not always be the best idea, codes/regulations change and some cities will grandfather in stores with, let's just say a hood, which no longer meets current code, if you do what they have done it will NOT pass new code, you will not collect \$200.00 and you will not be issued a permit/license. Even the type, location and size of your signage will come under the codes department and it will cost you \$\$\$\$\$. It will seem like everybody you meet will have their hand out and it won't be to shake your hand! :-D

[Re: Opening up a pizza shop.](#)**224**

It "can" be a solution BUT the "fly in the ointment" is that by doing so it is possible to reduce the yeast level sufficiently so as to reduce the oven spring characteristics of the dough which can lead to the development of the "dreaded gum line".

[Re: iced water for flour with ascorbic acid](#)**225**

Before diving head first into heat n' eat pizza I would HIGHLY encourage you to thoroughly test your concept. There is a reason why essentially all of the ready made pizzas available in the frozen foods case are made on par-baked crusts, the reason being that it is extremely difficult to heat the entire pizza (crust and toppings) properly without over doing one or the other. Added to the challenge is the vast array of different types of consumer ovens in use and you can see a problem brewing. Additionally, be sure to check on all of the state and Government regulations that you will need to abide by. For example, if you will be putting meat on your pizzas you will be USDA inspected, and have a USDA inspector on premise at all times during production (this will be at YOUR cost too). Just giving you a "heads-up".

[Re: Freezing dough](#)**226**

They certainly will spoil and possibly in a worse way than a yeast leavened dough. Flour has a relatively high possibility of being contaminated with Ecoli or Salmonella (just look at the number of recent flour recalls), without the acid and alcohol production of the yeast it is entirely possible for these, or other, organisms to eventually grow in the dough, true, baking will destroy them but not before creating havoc through cross contamination. For a refrigerated dough it's probably not a good idea to hold it more than a week due to the possibility of microbial growth and a higher than normal probability of mold growth which only takes about 4-days to colonize.

[Re: Question about yeast-less doughs?](#)**227**

Most shops just reheat the slice right on the deck. It's common for some debris to collect on the deck surface but this is easily removed using an oven rake and brush

(metal blade scraper on one side and a brush on the other side).

[Re: Pizza slice reheat](#) **228**

Now you know why I always say to lightly oil the top of each dough ball after placing it in the dough box. It keeps it from drying out during the cross-stack period and also when you're using the dough balls to make skins.

[Re: Keep Crust from Forming While Dough Balls Wait for Stretch?](#) **229**

Ditch the "dough in the freezer" approach, instead either store water in the cooler or do as Amolapizza suggested. The easiest way to make your own crushed ice is to put ice cubes in a plastic bag and pound on it with a hammer or mallet, instant crushed ice! ;D

[Re: iced water for flour with ascorbic acid](#) **230**

I can't tell for sure without getting my hands into the dough but from the pictures provided, it looks like the flour might be over oxidized.

This is a very common problem with flour that is not stored in the freezer. Five gallon buckets are fine for storing flour in but it does not address the oxidation issue. Flour oxidizes naturally as it is stored and is pretty significant already at 30-days for a flour that is not treated at the mill with AA (ascorbic acid). We had some discussion on this very topic some time ago if you want to go back and research it in the archives.

[Re: Neapolitan dough problem](#) **231**

You open the box and release the humidity trapped in the box, then repeat, repeat, repeat = dry dough balls. The very thin plastic film easily drapes over the individual dough balls and because it is a smaller space the moisture loss is less when the plastic is moved. It's almost like having each dough ball in its own individual plastic bag or dome as opposed to the large dough box. Dough boxes are really designed for use in pizzerias not home use.

[Re: Keep Crust from Forming While Dough Balls Wait for Stretch?](#) **232**

You bet it makes the slice more crispy to put it back in the oven to re-freshen it! Putting the fresh baked pizza on/in a pan doesn't do anything to encourage a crispy crust either. It's better to place it onto a screen where it can freely steam off as opposed to a solid pan which will force the steam back into the crust. Ripple sheets also work well for this application too.

[Re: Is it possible to get a crispy bottom crust in a home oven \(without par-baking\)?](#) **233**

The flour actually encourages the development of a dry skin or crust as it dramatically increases the surface area. I really don't like the damp towel either as it can cause the dough balls to pick up more dusting flour and make it harder to get it off, instead, try using one of those very thin, light weight plastic bags that you get from the dry cleaners, these bags are about as light as those that you get at the supermarket for your vegetables. You can split these bags open and use them too. Just drape over the dough balls to prevent drying, you can then remove just one dough ball without uncovering all of the rest.

[Re: Keep Crust from Forming While Dough Balls Wait for Stretch?](#) **234**

Please explain to me how freezing a par-baked crust removes moisture from it as opposed to allowing it to set out on a rack at room temperature?

[Re: Airy Sicilian style?](#) **235**

Something to keep in mind, most ovens are not specifically designed to be used with steam. Steam creates a number of issues in an oven, the greatest is that it will mix with the byproducts of yeast fermentation (acids, alcohol and carbon dioxide) which are then carried to all internal parts of the oven where they are concentrated as the moisture evaporates, these acids can/will do irreparable damage to an oven in a very short time. I realize that this is in a home setting but the damage can still occur, just making you aware of this.

[Re: Steaming your Pizza during parbaking? \(Home Oven\)](#)**236**

One of the manufacturer recommended methods for adding IDY is to add it to the dough after the dough has formed in the bowl. We normally don't recommend that method only because we have found that all too many times one will forget to add the yeast..Oops! :o

Amylase has no impact upon the dough temperature at the mixer. You should always be targeting a specific finished dough temperature that is correct for your shop conditions, equipment and dough management procedure, this might mean that you will need to use ice water, refrigerated water or possibly even ice as part of the total water weight.

[Re: iced water for flour with ascorbic acid](#)**237**

Be sure to provide your dough formula as well as your dough management procedure and give information on the oven that you have as well as the finger profile it is equipped with, the baking time and temperature and what you are using for a baking platform (pan, screen, disk, etc.).

[Re: Oven problem or dough problem](#)**238**

Doing the easy thing first, the first thing I would do is to reduce the oven temperature to something in the 475 to 500F range and try baking the pizza a little longer (7-minutes is a good target time).

[Re: Help getting bottom crispier please](#)**239**

The reason for using steam in the oven for baking certain types of breads and rolls is not for heat transfer, but instead to cool the outer portion of the dough (crust portion). Since the dough is much cooler than the steam (212F/100C) you get condensation forming on the surface of the dough which both cools the dough (actually keeps it cooler for a longer time during the baking process) which prevents the crust from forming and allows for greater expansion (oven spring) during baking. The condensation on the dough also serves to keep it flexible and extensible which allows for expansion without the dough tearing or developing a break and shred.

In commercial production of par-baked crusts and buns (think of those WONDERFUL dinner rolls we'll be serving at Thanksgiving dinner) it is a common practice to use some steam injection in the oven during baking to allow the crusts and buns/rolls to be fully baked without crust color development, or at least minimal crust color development. This is because the evaporating moisture from the dough prevents the surface from reaching the 350F/176.6C necessary for color development while still allowing for a thorough bake with an internal temperature of 180 to 190F/82.2 to 87.8C. When some color development is desired the steam is used only for the first part of the baking cycle which allows the dough to dry off and reach a temperature where crust color can begin to develop.

[Re: Steaming your Pizza during parbaking? \(Home Oven\)](#)**240**

Since "00" flours are not typically compatible with home oven baking temperatures I would suggest putting the "00" flour aside for now and using only a malted flour with about 12% protein content, then when you get a crispier crust you can begin experimentally replacing a portion of the regular flour with your "00" flour. Allow the dough balls to CF for 48-hours. You should be OK at 500F, tell us about the stone that you are baking on, there are many iterations of baking stones and it helps to know what you are using. Also, how long do you allow the oven and stone to preheat? Where is the stone positioned in the oven? Tell us something about your oven too. What is your baking time? Lastly, when you say the crust isn't crispy, how long after removing the pizza from the oven are you making this determination?

[Re: Is it possible to get a crispy bottom crust in a home oven \(without par-baking\)?](#)**241**

For that small of a dough you certainly don't want to mix the dough at a slower speed. You would get better mixing action with a larger size dough.

[Re: Is my kneading speed good ? \(stand mixer\)](#)**242**

I'm unable to access your video but if you are mixing at speed #3 on a 5-speed mixer it should be OK. Specifically, what kind of mixer do you have? Can you send a picture of it along with the dough agitator?

[Re: Is my kneading speed good ? \(stand mixer\)](#)**243**

Using 500-gram dough balls you can probably pattern the dough balls 3 X 5 (15 total count) on a sheet pan. Space four plastic spicr bottles on the aheet pan between dough balls to act as a spacer to allow for stacking another sheet pan above it. By the way, your total dough absorption is 64% (not 65%) with 1% oil.

[Re: Cold Ferment Plastic Bag Method Advice](#)**244**

Just how long have you had the flour which you are now using?

[Re: Neapolitan dough problem](#)**245**

If you are going to CF (cold ferment) it's best to take the dough directly from the mixer to the bench for scaling and balling, then directly into the fridge and leave it there for the duration of the CF time, then, if you want to do some RF (room fermentation) you can do it at that time and use the dough when that's finished. Going back and forth between CF and RF serves no useful purpose except when working with previously frozen dough, but that's a whole different story.

Keep in mind that all pizza doughs do not have to double in size, some doughs show little movement over the entire fermentation period but still make a great crust. Putting a sufficiently large "bulk" dough in the fridge only leads to variability in the dough as only the outer portion of the dough gets sufficiently cooled to control the rate of fermentation while the core remains warm and continues to heat up and merrily ferment away, giving you two different doughs at the end. By breaking the bulk dough down into individual dough pieces and forming into balls you get smaller dough pieces with a smaller cross section which are more effectively cooler to a temperature where the fermentation rate can be effectively controlled which in turn, results in greater uniformity/consistency in dough performance.

It might be well to note that a "bulk" dough weighing less than about 2-pounds performs more like a dough ball in the fridge than a true bulk dough that weighs more than two pounds and has sufficient mass to perform like a bulk dough.

[Re: Ideal rise at RT and CT? When to move?](#)**246**

T-P-D;

You've got the right approach, I'm betting you'll be enjoying some good pizzas along the way. Just remember to take notes and record temperatures along the way and take some pics to share. :chef:

[Re: Struggling and unsure what ...247](#)

We used to refer to shortening as "glue" to hold the dough in place while its in the pan.

Before anyone asks, NO, it doesn't cause the baked crust/pizza to stick in the pan.

[Re: Silly question, dough sliding back down on the sides248](#)

You should be mixing at a speed sufficiently high to allow centrifugal force to pull the dough off of the agitator during the mixing process. You might go to my web site <www.doughdoctor.com> and watch my video on making dough to get an idea of how this is done.

[Re: Dough issues during stand mixing249](#)

Placing a fermented dough ball in the fridge isn't going to do much to control the rate of fermentation. The fermentation has reduced the density of the dough making it an excellent insulator which will prevent much, if any, temperature change in the critical core of the dough ball. You might see that the dough ball isn't expanding as much in the cooler but this is only due to the now colder outer portion of the dough ball exhibiting resistance to expansion, the internal core is still warm (may actually be getting warmer due to heat of metabolism) and fermenting. This is why, in commercial practice, we open over fermented dough balls into skins that are then placed on screens and stored in the cooler, by doing this we significantly reduce the cross section of the dough/dough ball thus allowing it to be more effectively cooled all the way through as opposed to just on the surface.

[Re: Ideal rise at RT and CT? When to move?250](#)

We got the best results between 15 and 30% masa flour to REPLACE an equal portion of the white flour. It will impact the dough absorption so be sure to do an absorption test on the masa flour first (use the same absorption test that has bee outlined for whole-wheat flour and multi-grain blends).

[Re: Fritos corn chips in dough???251](#)

Your mixing speed is too slow for the dough size.

[Re: Dough issues during stand mixing252](#)

Absolutely! Use Crisco or some other form of plastic shortening. If you want to use oil use the Crisco only on the side walls of the pan and use oil in the center section. To demonstrate this during our pizza seminar we used to prepare one pan with shortening and one pan with oil, then pick up both pans and invert them, plop! The dough in the oiled pan would just fall out while the dough in the pan with the shortening would stay in place. It also makes fitting the dough to the pan a lot easier too, try it, you'll see what I mean.

[Re: Silly question, dough sliding back down on the sides253](#)

I've seen crushed corn chips used in the dough a number of times. In each case though the reason was to provide a unique flavor to the finished crust. You can achieve exactly the same flavor using masa flour/Maseca. This is because corn chips are made from a dough containing only masa flour, water and salt. The dough

is then rolled thin, cut and fried. In some cases a flavoring or powdered cheese is applied immediately after exiting the fryer. We have used it extensively in developing Tex-Mex style pizzas.

[Re: Fritos corn chips in dough???](#)**254**

Since there is no "true" definition for AP (all purpose) flour there are significantly different versions of it from different manufacturers. Some mill it from soft wheat varieties while others mill it from hard wheat varieties. Within the group that mill it from hard wheat varieties it can range from a low of 9+% protein content to as high as almost 12% protein content. If you can, go to the web site of the manufacturer to see if you can find the protein content or try Googling (what is the protein content of XXXX all purpose flour). Let us know what you find out.

A good flour to look for that is readily available is Pillsbury Bread Flour also called Pillsbury Bread Machine Flour. This is really just the Pillsbury Superlative Flour repackaged in a consumer size package. It has approximately 12.6% protein content and it constitutes an excellent all around/general purpose pizza flour.

[Re: AP flour](#)**255**

Raj1;

One other thing, I see in your photos that the conveyor chain is carboned up quite a bit, when was the last time you pulled the conveyor for a thorough cleaning and cleaned out the finger sleeves? Do you have a top and bottom finger map attached to your oven?

[Re: Dough not rising and too white](#)**256**

Raj1;

Based on cost alone, I would suggest increasing the sugar content rather than the malt, but if you want to increase the malt you can do so as long as the dough doesn't become overly sticky.

Let's talk ovens; Your oven specifically. It's an air impingement oven, who is the manufacturer of the oven? Gas or electric? Did you buy it new or used? What are the top and bottom finger profiles? It concerns me that you are baking your pizzas so long and not achieving decent color even with malt and 4% sugar in the dough formula. In my air impingement ovens I used to get plenty of color even at 3-days CF with just 2% sugar. It's an uphill battle if you try to fix an oven problem with dough formulation.

Can you show a picture of the crust that you said is now all white?

[Re: Dough not rising and too white](#)**257**

120 to 180 is a very high Lintner Value. I would suggest reducing the amount added to 0.05% of the flour weight and carefully working up from there if you can. We have had some discussion on Malt and Lintner value fairly recently, a quick search will allow you to learn more about this important aspect of the malt products that we use in pizza making.

[Re: Struggling and unsure what ...](#)**258**

Frying donuts at such a low temperature will result in a dry and oily finished donut. Yeast raised donuts typically have a shelf life of 4 to 6-hours (without additives), frying at a low temperature will further reduce this.

The corn starch is indeed a part of the powdered sugar, there is 3 to 5% corn starch in powdered sugar. The sugar used to make powdered sugar is dextrose, not sucrose.

There is no way to tell if putting a pot of water in with the dough would help at all

as there would be very little evaporation from a "pot".
Maybe wet towels?

You want to have a hygrometer to measure the humidity in the air. This is easy to make, use two stem/dial type thermometers, two Styrofoam cups and a piece of paper hand towel. Put one thermometer through both sides of a cup (this will be the dry bulb). Push the other thermometer through the other cup about 2-inches up from the bottom of the cup. Add a few ounces of water to the cup (water should be at or close to the air temperature in the box), now, wet a strip of the paper towel, wrap it around the stem of the thermometer allowing the two ends to drape down into the water, place both thermometers in the product zine in the box. After an hour, or so, read the temperature from both thermometers (the one with the wet towel is the "wet bulb" reading, the other one is the dry bulb reading. If you've done it correctly, the wet bulb reading will ALWAYS be the cooler of the two readings (due to evaporative cooling of the stem from the wet towel). Now get a RELATIVE HUMIDITY CHART (you can download one from the Internet), find your temperatures on the two axis lines and where they meet the number will be the relative humidity in the box. For donuts you want about 70% for most other things you want to have something around 85%.

[Re: Dunkin' Donuts Yeasted Donuts copycat](#)**259**

Sounds more like a "thing" to me. Trying to achieve a certain appearance.

[Re: pre-bake red sauce on cornicione?](#)**260**

Strange that the one thing you did not mention at all was dough temperature. As you've already discovered, fermentation has a huge impact upon the dough and temperature is the driver of fermentation, it's a variable that we seldom ever control or even monitor. If you have any data on your dough temperature as well as the temperature during the various stages of your dough management you should be able to plug those numbers back into the dough to see if that improves things, lacking that, you may need to begin experimenting with your dough (while keeping records of the dough and room temperature) to how temperature is impacting your dough. From your comment on the excessive elasticity I'm guessing that your bread machine might be getting the dough too warm, easy to check this out the next time you make dough. I'm guessing that you should be looking for a finished dough temperature (off of the bread machine) around 70 to 75F. That's a neat trick for most bread machines which is why I got rid of ours years ago.

[Re: Neapolitan dough problem](#)**261**

75 to 80F is much too cold for hydrating and activating the ADY in, I suggest using 95 to 100F water.

Degree L is the Lintner Value use for measuring the diastatic activity of the malt. Too much of the wrong malt will result in wet, sticky doughs.

I really wouldn't call 55F as CF as most people think of CF being done at a refrigerated temperature in the 35 to 40F range. I mention this because if the process calls for CF and you are doing it at 55F your dough will receive significantly more fermentation than anticipated.

[Re: Struggling and unsure what ...](#)**262**

Oil and shortening both weigh the same so if you are asking how much oil to use when replacing the shortening the answer is: Use the same weight of oil as you do shortening. If you want flavor use POMACE GRADE OLIVE OIL as opposed to EVOO, you could also just use lard, trans free and if you use NON-DEODORIZED LARD it'll add a great flavor. Keep in mind that if you use oil it is recommended

that you use the delayed oil addition method of dough mixing.

[Re: Switching from shortening to oil](#)**263**

Fermentation is indeed the key to achieving a great flavored finished crust. How much fermentation is a question that only you can answer as it will be dependent upon the fermentation tolerance of your flour, the dough absorption, the amount of yeast being used and the temperature of the dough during the time it's being managed and then we also have to add baking. Lots of variables there! Without knowing anything about what you are doing here is what it's going to take;

1) Weigh all ingredients.

2) Measure the temperature of the water, flour, room and finished dough temperature.

3) Know how long the dough is being mixed so you can replicate it.

4) When you are using a multi-stage dough management procedure as you are be sure to record the time between each step and if applicable, the dough temperature.

5) Record everything and keep good notes.

By doing this, when you get something that you really like you will know exactly what you did and you will be able to retrace your steps to get to that place again. It will also allow you to look for short cuts to that sweet spot without losing track of knowing exactly where you are at in your dough making process.

[Re: Maximize flavor](#)**264**

I have a couple of questions:

1) What is "DCL Active"?

2) Diastatic malt: What degree L is it? Is this a dry malt powder or a syrup?

3) Have you tried making a dough with less dough absorption? I'd suggest dropping back 5% on the absorption.

4) I did not see where you are activating the ADY in 95 to 100F water prior to addition to the dough.

[Re: Struggling and unsure what ...](#)**265**

My recommendation is to wash the screens but DO NOT ALLOW THEM TO SOAK IN SOAPY WATER, rinse well, towel dry and then force dry in the oven. After that, coat with salad oil and place back in the oven at 425F. and allow to bake for 20 to 30-minutes. You might need to repeat this a couple of times. At first you will see an amber colored finish beginning to form, this is the seasoning, after the initial seasoning you will not need to do it again. With continued use the screens will continue to darken in color and eventually become almost black in color (this is what you are looking for) DO NOT bake on an unseasoned screen, if you do the screen and dough will stick together. Once seasoned, NEVER EVER, EVER soak anything that has been seasoned in water!! This will cause the seasoning to come off like a bad sunburn. We have discussed how to season and clean seasoned pans a number of times here.

[Re: Pizza Screens shedding](#)**266**

I think the first thing I would do is to shelve the volumetric portions and get a scale so I could weigh my ingredients and then pick up a dial/stem type thermometer. This will allow you to accurately weigh each of your ingredients and measure dough temperature at the various stages of your processing allowing you to zero in on achieving the results you're looking for without the need of using the old pasta on the wall methodology.

If you can provide us with your "recipe" and dough management procedure we

might see something that would help us in providing you with a good starting point to get the open crumb structure you're looking for.

[Re: put the pizza pan directly on the heating coil?267](#)

Pizza dough is made from a pretty basic dough formula such as:

Flour: 100%

Salt: 2%

Yeast (CY): 1%

Water: 62% (variable)

In this case sugar and oil are optional ingredients used for specific purposes such as making a more tender eating crust or providing for more crust color or nutrient for the yeast.

To the above formula add 4% oil and you have a great deep-dish/thick crust formula.

Use the formula as shown to make a basic thin crust dough.

Increase the water to 68% for a New York style pizza.

You can also make a somewhat Neo. style pizza by increasing the absorption to 75%

If you want to make a basic pizza that will emulate those made by the big box stores just make the dough with 2% oil and 2% sugar and you can get pretty close by manipulating the dough management procedure.

It's when we begin making specialized types of pizzas that we really need to have more specific dough formulas for the pizza being made. If you want to make a more traditional Neo. type of pizza you will need to reduce the yeast level substantially and manage the dough in a very different manner for the desired outcome. Most American style pizzas are not very complex at all and most seem to fall within pretty close formulation parameters, even the dough management procedures for American style pizzas do not vary all that much which explains why they tend to be so similar regardless of the name on the store front.

[Re: The reasons for different types of dough268](#)

When you put the salt into the dough water the dough comes together a bit faster in the bowl during the mixing process as a result of the salt tightening the gluten as it is being formed. When salt is added as a dry ingredient it can take a minute or so longer for the dough to come together forming a cohesive dough. In home pizza making this is not an important issue but in a commercial setting, be it a pizzeria or a commissary, this can be very important in determining how the dough is mixed.

Because the dough becomes tighter in the presence of salt it receives more mixing action sooner during the dough mixing process thus developing gluten at a somewhat faster rate. The premise to this is that firm/tight/stiff doughs tend to develop gluten at a faster rate than very slack doughs.

[Re: Very airy dough269](#)

AntonioT;

That's a classical example of what I always tell perspective new pizzeria operators; "You don't have a vote in the type of pizza you will make, your customer will dictate that, your job will be to make that pizza and put the money in the bank".

[Re: soft neapolitan corniccione270](#)

Two things that you can do;

1) Some brands of non-frozen mozzarella cheese will turn tough and chewy when frozen, so you might try freezing your cheese for a week or two prior to use to see if your cheese is one of those brands.

2) Open your cheese and re-wrap it in Saran Wrap/stretch wrap and store it in the fridge for about 6-weeks before using it. This allows the cheese to dessicate, resulting in a much chewier cheese after baking on the pizza.

Many of the older cheeses were never frozen, just refrigerated and when the pizzeria operators stored the cheese in the freezer or held it too long in the cooler it gave the chewy characteristic. Today most shops do not want the chewy characteristic as it poses too much of a potential choking hazard.

Now, if by "chewy" you actually mean "stretchy", take a look at provolone cheese as it tends to be more stringy than mozzarella.

[Re: Bake pizza so the mozzarella ends up with a chewy texture](#) **271**

I was just there last Sunday delivering a motorcycle!

Welcome aboard!

[Re: Allow myself to introduce....myself. - Lincoln, NE - Koda 16](#) **272**

The one thing that I find absolutely AMAZING about air impingement ovens is just how few operators know anything about them! They really don't have a clue as to how they bake, how the fingers work or the importance of the finger profile, or even what kind of different fingers are available for their specific oven. This observation doesn't necessarily stop at the owner/operator either, it also flows back to the oven manufacturers too. I personally, have been very critical of this for a good number of years now and I can say that there are some of the manufacturers who are very good at working with their customers to find the best finger profile for their client's pizzas but there are still some out there who insist upon selling you an oven with a generic, one size fits all, finger profile which may or may not work the best.

When you toss in used ovens you are opening a Pandora's Box if you don't know EXACTLY what the top and bottom finger profiles are. Air impingement ovens are just that, they are "OVENS", nothing more, nothing less, they can be profiled to bake many different food items from seafood, cookies, bagels, and even pet foods, it all depends upon how the oven fingers are profiled. When these ovens turn up on the used equipment market they are sold as, you guessed it, PIZZA OVENS! It sure looks like a pizza oven, so it must be one...right!!

Deck ovens are not as prone to these issues, they are pretty straightforward to operate with only the baking temperature being a variable BUT don't forget that this can also pose problems too, these ovens can last a long time and over time the temperature management systems will fail and need replacement, I see this frequently. Then too, going back to the used equipment market place, all deck ovens are NOT pizza ovens! There are some deck ovens, especially those with steel decks, that were built for use in a small bakery or restaurant for baking bread and pastry items, not pizza. These ovens have smaller burners than those ovens built as a pizza oven so they will bake a few pizzas but lack the ability to retain baking properties under a continuous load. For good measure let's also look at electric deck ovens, especially those getting "long in the tooth", I've seen my share of these ovens from different manufacturers that just wouldn't bake a decent pizza because

the heating elements were failing, so based on this alone, one might assume that electric deck ovens are not the best for baking pizzas either.

It's easy to draw the wrong conclusions when we don't have all the facts. A number of years ago I wrote an in-depth article on the different types of ovens for either Pizza Today or PMQ, I don't remember anymore which one it was, but maybe Peter can work his magic and find a link to the article if anyone is interested.

[Re: "Good pizzas are 90% oven" "conveyor ovens are not great" Oven primer for newb](#)**273**

Raj1;

Yes, there is an "emergency" dough procedure but I don't recommend its use as you have outlined as it is too different from your regular production dough. Instead, it is intended to be used in situations where all of your regular dough has been lost, forcing you to close the store, in this case the emergency dough will allow you to remain open. We always tell our clients to manage their dough in such a manner so as to have carry-over dough at the end of the day which can be used on the following day. Let's say your best day of the week is 100 pizzas, you always have an inventory of 15% greater than this on each night of the week and when you make dough make just enough to rebuild your dough inventory back to the 100 + 15% (115). This is where an Effective Dough Management program is worth its weight in gold in a commercial operation as it allows you to use your dough over a 2 to 3-day period and never toss out any dough unless it hits the floor. Sales/dough projections and dough management are critical aspects of operating a pizzeria.

[Re: Emergency dough](#)**274**

For all practical purposes, fermentation begins as soon as the dough begins to mix and ends with the cessation of oven spring when the dough temperature reaches the thermal death point of the yeast (approximately 137F). Keep in mind that when discussing dough management total fermentation time includes both the dough fermentation and dough proofing times. Dough proofing is the time allowed for the dough to rise after shaping, for example a deep-dish pizza dough might be fermented for 24-hours, and then shaped and placed into the pan and allowed to proof for an additional 60-minutes before dressing and baking. If a dough is fermented in bulk or as a dough ball it doesn't matter, it's still referred to as the "fermentation" period. When cold fermenting, the time that we allow for the dough balls to warm up after removal from the fridge is not counted as fermentation or proofing time since the dough is too cold to ferment very much during this relatively short period of time, this is ASSUMING that the dough is being allowed to temper to the 50 to 60F range before opening, dressing and baking.

[Re: Trying to understand some things I've been doing for years, but never asked](#)**275**

And to add a few logs to the fire;

What was the finished (mixed dough temperature)?

You said the dough was wet, did you leave the containers open until the internal dough ball temperature reached 50F?

After removing the dough balls from the fridge you only need to wait for the INTERNAL dough ball temperature to reach 55 to 60F before opening them into skins....4-hours was waaayy too long.

You will also want to get a scale so you can begin weighing your ingredients, this will also allow you to put your dough "recipe" based on volumetric portions, into a

dough formula, based on ingredient weights which can then be expressed in bakers percent to make evaluation of the dough formula much easier. By weighing your ingredients you will have significantly better consistency in dough performance too.

[Re: Dough is not light and fluffy](#) **276**

Amolapizza;

That's an EXCELLENT video! Shows correct dough development with the spiral mixer and also shows effects of biochemical gluten development.

Thank you for making it and sharing it.

[Re: Popping dough](#) **277**

Not at all, it sounds like you might be making a fairly low absorption (50's %) range dough.

[Re: Popping dough](#) **278**

That's how you tell the "good guys" from the "bad guys" in the old western movies too, the good guys are always wearing white hats. :-D

[Re: Superstitions?](#) **279**

The sooner you can freeze the dough balls after mixing the better the finished results will be. The procedure that I developed for commercial frozen dough balls is as follows:

- 1) Slack-out (defrost) dough balls in the fridge for 12-hours.
- 2) Remove from fridge and allow to set at room temperature until the INTERNAL dough ball temperature reaches 50 to 55F (pick a temperature).
- 3) Place back into the fridge to CF for 24-hours.
- 4) Remove from fridge and allow to set at room temperature until the INTERNAL dough ball temperature reaches 60F.
- 5) Begin opening the dough balls into skins for immediate use.

[Re: Freezing dough ball question](#) **280**

It appears that the top of the pizza still needs a lot of work which is beyond the dough, or is that a par-baked crust which has been dressed and ready to go into the oven?

[Re: Pizza steel experience and what went wrong.](#) **281**

The photo (12 of 16) showing four pan different black colored steel pan options shows what appear to be very similar to your existing pans, the second one from the right and the last one (#4) from the right. Get a few in the sizes that you need and give them a try.

[Re: Margarita pizza](#) **282**

Start out at 62% absorption again and adjust if necessary, don't ever be afraid to adjust the dough absorption, flour is rather variable when it comes to absorption, especially the Caputo flours.

[Re: Dough balls too flat](#) **283**

It's perfectly safe to eat yeast just as it is (in moderation). I know individuals who actually eat raw yeast believing that it's good for them. I don't know about that, but they're healthy. For me, I'll take a pass on the raw yeast and consume it after it has been allowed to do its work in fermenting the dough and getting killed during the baking process (much more tasty that way). In any case, there is nothing to fear in

eating raw yeast in moderation or any amount of spent yeast in baked dough.

[Re: Yeast increase](#)**284**

The one caveat is that you want to leave enough water/moisture in the mushrooms to prevent them from burning during baking of the pizza. Remember, mushrooms are approximately 90% water by weight. I've seen pizzas made where the mushrooms were too low in moisture content going onto the pizza and after baking the mushrooms were all but black.

[Re: Vegetarian pizza](#)**285**

Has your starter been stored under refrigeration since you started it? Most starters do not perform well at refrigerated temperatures but if you have kept the starter at refrigerated temperature the micro-flora present in the starter has adapted and will continue to flourish under those conditions whereas if you have stored it at ambient temperature (whatever that might be) it will not fare as well when held under refrigerated temperature (40F +/-).

[Re: Sour dough starter question](#)**286**

The deep-dish pans have plenty of color on the outside bottom, but the other pans don't and that could be a contributing factor to your long baking time.

[Re: Margarita pizza](#)**287**

I personally don't know of any manufacturers still using galvanizing, instead they are all using TIN PLATE which is very different from galvanizing, with none of the safety issues either.

[Re: Dishwasher safe serving pans](#)**288**

You should not need to adjust the dough absorption seasonally, ditto for the yeast level but only if you are managing the dough correctly, by this I mean targeting a specific finished dough temperature (70F/21.1C is a good starting point) and maintaining that temperature for all of your doughs.

[Re: Yeast increase](#)**289**

The aluminum pans get discolored due to a reaction between the alkali in the soap and the aluminum. This is especially bad with raw/bare aluminum pans. Anodized aluminum has the protective anodizing so the problem isn't as bad until the anodizing is worn off and considering the pan will be used for table service that might happen sooner than later. Steel pans are galvanized to protect from rusting so they don't suffer the same fate but over time rusting could be a potential issue.

[Re: Dishwasher safe serving pans](#)**290**

It looks like pictures of two different types of pans, deep-dish pans and what appear to be similar to what we call a "cutter" pan (40 degree sloped sides). The cutter pans from what you sent are bright on the outside bottom, they should be dark colored like the inside of the pan. The deep-dish are well seasoned on the inside but there doesn't appear to be a picture of the outside bottom so I can't tell.

[Re: Margarita pizza](#)**291**

I might be a bit concerned about using sugar or malt at the high baking temperature employed here, but it's always worth a try.

[Re: soft neapolitan cornicciione](#)**292**

Absolutely! The amount of actual ascorbic acid used is only 30 to 120 ppm (parts

per million) based on total flour weight. When we use it in tablet form each tablet (about the diameter of a dime and 1/4-inch thick) provides 30-ppm, the rest of it is filler too.

[Re: Dough Conditioners/Enhancers](#)293

I couldn't agree with you more ^^^

My "go to" flour for making pizza is 12.2% protein content on average.

[Re: High Gluten Flour](#) 294

While the bricks will be a bit hotter than the air above the bricks the main reason for what you saw was due to the type of heat transfer taking place. Conduction due to direct contact with the hot object allows for very rapid heat transfer, convection due to contact with the air is a pretty poor heat transfer mechanism. This is why even though a commercial deck oven might be baking pizzas at 525F we can safely reach into the over without getting burned, just DON'T touch anything in the oven! When you bake those cookies on a raised rack above the bricks you change the type of baking from conduction to convection.

[Re: Pizza comes out soggy in the middle...](#)295

While both whole-wheat and semolina flour are indeed included in the dough absorption equation they must be calculated separately from the regular white flour. This has been discussed along with a procedure on how to do it previously here, a quick search through the archive will take you to it.

[Re: Semolina and whole wheat flour in formula](#)296

As a point of interest, those pics above look just like what we were demonstrating to our students, additionally, you see in the pics what appears to be darker/less translucent areas within the dough sheet, those areas are referred to as the "gluten web structure" or just "web structure". This is important to know as it is an indication of gluten development, the finer the web structure, the better/greater the gluten development. Both pics show EXCELLENT and very complete gluten development.

[Re: High Gluten Flour](#) 297

One thing to be aware of is that while ascorbic acid is indeed the same as vitamin-C the forms used in a dough to act as a "dough improver" are NOT the same. The form of AA used in dough conditioners or as a dough conditioner is either fat encapsulated or micro-crystalline encapsulated to slow/delay its reaction in the dough. Ascorbic acid reacts very fast unless treated in this manner thus significantly reducing its benefit as a dough strengthener. When added at the flour mill (this is the AA that you see shown on the flour bag) it is added to rapidly oxidize the flour so it is not treated/encapsulated. This is important as it improves the baking properties of the flour. When flour is not properly oxidized after milling it is referred to as "green" flour. Before the advent of ADA and AA the bakers used to store their flour for 30-days or more to allow for normal oxidation to take place....not very practical anymore to say the least! This natural oxidation also explains why flour that is milled towards the end of a crop year tends to show stronger characteristics than new crop year flour (wheat berries, not just flour will naturally oxidize), and it also explains why if we, at home, store flour at room temperature can find that for some strange, unexplained reason the flour seems to become stronger, now you know why, natural oxidation is the answer.

[Re: Dough Conditioners/Enhancers](#)298

Raj1;

No, if it did you would have dehydrated mushrooms. You are just reducing the moisture content. In commercial applications we use moisture controlled vegetable toppings with excellent results. The DiGiorno brand of frozen pizzas utilize the moisture controlled IQF (individual quick frozen) toppings. They retain color and texture much better than fresh toppings making them especially well suited to use in frozen pizzas.

[Re: Vegetarian pizza](#)**299**

Due to their high sugar content cookies will burn, especially when placed directly on the stone just about every time they see temperatures above the 350 to 400F mark. If you look at the bottom of most cookies you will see that the bottom is a bit darker than the rest of the cookie except for the rim which is sometimes also dark due to lateral heat penetration. To bake cookies with balanced color it is common to remove the cookies from the oven before they are fully baked they are then allowed to cool on the baking sheets during which time the cookies finish baking from the latent heat stored in the baking sheet. Point is, cookies are a poor test media for a pizza oven, the one thing you did learn from the test though is that while the bricks remained hot the air in the oven did not as the top and bottom color were different. Remember too that the crown height and shape in an oven has a huge impact upon how that oven will bake different products.

[Re: Pizza comes out soggy in the middle...](#)**300**

What you have is pretty standard for a NP pizza.

A couple of things you might try are as follows:

- 1) Brush the edge with oil immediately prior to baking.
- 2) If you can "dome" the pizza in your oven this might also help.
- 3) As soon as the bottom of the pizza is baked place a screen under the pizza to allow for a longer baking time.
- 4) Change direction and make a New Haven style pizza.

[Re: soft neapolitan corniccione](#)**301**

I would begin my search by looking right here, over the years we have had a lot of discussion on different types of flour that can be used to make pizza. While typical bread flours are appropriate for making pizza the reverse cannot be said for making all types of breads. Pastry flours are a totally different animal as they are generally made from soft wheat varieties which form a much softer/weaker gluten structure necessary for the tender eating characteristics associated with pastries. Then there are cake flours. There are two basic types of cake flours, high ratio cake flour for use in cake formulations where the sugar is greater than the flour. These flours are chlorinated AKA chlorinated cake flour. The other cake flour is for cake formulas where the sugar is equal to or less than the flour AKA low ratio cakes. Low ratio cake flours are typically the same as a pastry flour but are usually milled to a finer particle size, however for home use an all-purpose flour will work just fine for making low ration cakes. Then there is whole-wheat flour, when it's made from hard red winter wheat or spring wheat varieties it is known as whole-wheat flour and it is commonly used in breads, rolls, buns, pizzas either in total or in part. When the whole-wheat flour is made from varieties of soft wheat flour it is known as "graham" flour. Yes, graham crackers are made from whole-wheat flour and it is used in pastries, cookies, and just about any other type of baked product not requiring a lot of strength/gluten. On top of this, there are hard red wheat varieties where the wheat berry is a dark mahogany to brown in color, the color is due to tannin which gives the wheat a somewhat bitter taste, then there are hard white

wheat varieties (only type of wheat grown in Australia) which is growing in popularity here in the U.S. due to its greater acceptance as a whole-wheat flour owing to its reduced tannin content making the flour less bitter tasting, lastly, you have spring and winter wheat varieties. Due to the different climatic conditions/geographic regions that the wheat is grown in some areas grow winter wheat which is planted in the fall and harvested in the following summer. In colder regions the wheat is planted in the early spring and harvested in the early fall to late summer, this is known as spring wheat. Typically, spring wheat varieties will have a higher protein content than winter wheat varieties but they will perform equally on an equal protein basis. That's it in a nutshell, now you can read up on the finer details to learn more about each.

[Re: Flour](#)302

Wow! Dough conditioners, there are sooooo many different kinds of them. Some make the dough softer and more extensible, some make it tighter and less extensible, some make it feel drier, some make it stronger and then there are the enzyme based dough conditioners and the non-enzyme based conditioners. Whatever else is also in that bag of flour that you've got aside from "wheat flour" by law, has to be shown on the bag label. In the past we used to see potassium bromate added to the flour as a flour improver, not a dough conditioner but due to health concerns we don't see it used nearly as often as we used to. We still see a lot of ascorbic acid being used as a flour improver so it's pretty common to see it on the label. Then too we used to see Maturox on the bag label too (azodicarbonamide) but even that has fallen from favor in the past few years. Many flours are malted so malted barley flour will often be seen on the bag label however that is now being replaced by the addition of amylose enzymes to the flour, so now we often just see "enzymes" listed on the label. Then there is the standard flour enrichment declaration that most flours will have as many states require that all flour sold in their state be enriched to Federal standards. Whole-wheat/whole-grain flours are exempt from this requirement since non whole-wheat flours are enriched to the same vitamin and mineral content as whole-wheat flour. Today, for the most part, the only difference between white flour and whole-wheat flour is the bran/fiber content contained in the whole-wheat flour.

One other thing, because there are so many different kinds of dough conditioners with different functions a dough conditioner is never randomly added to any flour, it is added only to address a very specific issue associated with the dough. I used to tell my students to think of dough conditioners as medicine for the dough. You have to know what's ailing the dough before you can prescribe a medicine (dough conditioner) to address the problem. When working in Mexico back in the 70's I used to bring an assortment of different functioning dough conditioners with me. To facilitate handling the ones I brought with me were all in tablet or gelatin capsule form and once I knew what the issues were with the dough it was easy for me to select the correct dough conditioner and add it to the dough, these became known as "aspirina para la masa" (aspirin for the dough) and since I was the one giving them out I became known as the "El medico para la masa" Literally translated: The Dough Doctor, the title stuck.

[Re: Dough Conditioners/Enhancers](#)303

With those conditions water stored in the walk-in over night would be a good place to start.

[Re: Neapolitan dough in a spiral mixer](#)304

I make egg plant lasagna frequently so why not pizza? I've not done it, but it

sounds interesting with lots of opportunity to experiment.

[Re: Eggplant as sauce?](#)**305**

Raj1;

Your temperature is OK but the baking time is much too long. I'm betting the problem is with your pans being too light in color, can you send a picture of your pans so we can see what the bottom and outside look like? A more typical baking time would be 6.5 to 7-minutes max. This will probably correct the cheese issue too. If it doesn't the top finger profile will most likely need to be changed to something flowing less air.

[Re: Margarita pizza](#) **306**

I'm betting that you didn't bake it at a temperature north of 800F. That's what it takes to bake a pizza made with Caputo 00 without any added sugar or diastatic malt in the dough formula.

[Re: Pizza steel experience and what'r wrong.](#) **307**

Assuming you would be static freezing the dough (0 to -15F) with little to no airflow, you can freeze the dough with a projected frozen shelf life (use it or lose it) of about 10-days. For anything longer than that you will need to go with blast freezing (-25 to -38F with airflow of 600 to 800 linear feet per minute or cryogenic freezing (liquid carbon dioxide or nitrogen) with pressure adjusted to give -45 to -55F in the product zone plus a holding freezer at -15F to allow the frozen product to equilibrate to a core temperature of 0 to +15F within 90-minutes of exiting the cryogenic freezer.

Vacuum packaging is NOT recommended due to the potential for clostridium growth.

[Re: Freezing pizza dough](#) **308**

The diastatic malt (450-grams for \$6.75) is the one to use. They don't appear to provide any information on the L-value so I would suggest starting out at 0.25% and going up from there if necessary.

[Re: Dough not rising and too white](#) **309**

I like to think of focaccia like a bread, where you have to allow the dough to proof/rise in the pan before baking.

[Re: Focaccia rising in pan](#) **310**

IR thermometers are fine for all but the internal dough ball temperature measurements, for that I recommend a low cost dial/stem type thermometer. Make sure it has a hex nut under the head/dial, this is the adjustment nut that is used to calibrate the thermometer.

To calibrate, use an oral thermometer available from any pharmacy at low cost, adjust the water temperature to get a temperature reading on the oral thermometer, note the temperature, place the stem of the dial thermometer in the glass of water holding the oral thermometer, note the temperature shown on the dial, if necessary adjust the temperature so it reads the same as the oral thermometer, now you're good to go.

[Re: Neapolitan dough in a spiral mixer](#) **311**

When you open the door of a home oven and place a pizza in the oven, don't kid yourself, the oven takes a BIG hit and the burner is not designed for rapid recovery, instead, it's designed to be economical and have a 20 Energy Star rating.

Commercial ovens can have a burner with a greater BTU capacity than most home furnaces and they are designed so as not to lose very much air/temperature when opening the door, plus they have a lot more thermal mass than a few bricks. I'm betting that your pizza will take close to twice as long to bake in your home oven.

[Re: Pizza comes out soggy in the middle...312](#)

Get the specifications for the diastatic malt that is available to you and let us see it, we can then direct you on its use. Typically, you will be looking for a 20 degree Lintner Value dry malt powder, if you can get it it will be used at 0.25% of the flour weight. The only change to the dough formula will be to adjust the sugar content to 2%. The dry malt is just added right on top of the flour with no special handling.

[Re: Dough not rising and too white313](#)

If you are using the cheese from refrigerated storage (required by law as it is a food safety issue) the season of the year will not make a difference. Another trick to help control color development on the cheese is to mist the top of the pizza with water. Having an air impingement oven and with the issues you are having with the vegetable pizzas and your cheese getting excessive color I'm also guessing that the top fingers are not correctly profiled for YOUR pizzas. What is the baking time and baking temperature you are using and what is your baking platform (pan, screen, disk and what color is it)?

[Re: Margarita pizza 314](#)

If you saute the vegetables you will not have any of the problems you mentioned. Also, be sure to LIGHTLY brush the skin with a little oil before dressing it, this will help to retard the migration of moisture into the crust as it is being baked. This is an application where air impingement ovens really shine as they are very effective at removing moisture from the top of the pizza if the top fingers are properly configured. If you have a deck oven you can also bake at a lower temperature (450F/232C) to help dry off the top of the pizza.

[Re: Vegetarian pizza315](#)

My preference is for the AND /A&D Weighing scales, <www.andweighing.com> Their scales are about bullet proof, accurate and best of all they operate on common flashlight batteries.

[Re: Measuring scale316](#)

Your oven temperature is very low for baking pizza, 350 to 375 is better suited for baking cakes. Added to that, if the oven is not FULLY up to temperature it would really be difficult to get a decent bake on a pizza as the act of putting a pizza in the oven as well as baking will further drop the temperature creating a double "whammy" for you. My advice is to adjust the oven temperature up to 500F, allow at least 90-minutes for the oven to fully heat and stabilize in temperature and then bake, I think this will give you a much better bake if you are using a dark colored pan as an added plus, you won't need to wait so long for your pizza to come out of the oven so you'll be eating pizza sooner. ;D

[Re: Pizza comes out soggy in the middle...317](#)

Raj:

Your dough formula shows "yeast cake" at 0.5%, not 1 to 1.5%.

Also, the flour bag does not indicate any malting or use of enzymes, hence it is an unmalted flour. The only thing it has is some added enrichment.

[Re: Dough not rising and too white](#)**318**

When you say "larger" I don't know how large you mean but I've made pizzas up to 20" in diameter on my wood peels, that was also the largest diameter wood peel we had at the time, if we had a larger one I'd have used it too.

[Re: Perforated peel for large NY style pies?](#)**319**

It seems to be a love/hate relationship, some people love them, others hate them.

My own personal preference is for a good wood peel.

[Re: Perforated peel for large NY style pies?](#)**320**

Gene has a good idea there, try covering the box with a damp towel and then cover with the plastic wrap, I don't like the idea of spraying water in the box. Water + flour = GLUE (wallpaper paste).

[Re: Dough balls drying out on wooden boxes](#)**321**

I always let it rise in the pan before baking. What do you mean by "others will TIP the focaccia"? Did you mean "top"? I always allow the dough to rise in the pan before topping as this prevents any possibility of moisture migration into the dough during the proofing period.

[Re: Focaccia rising in pan](#)**322**

If your flour weight is 12.5Kg/12500 here is what your ingredient weight should be for the percentages you cited.

Flour: 100%

Sugar: 500-grams

Salt: 187.5-grams

Oil: 125-grams

Yeast cake/compressed yeast: 62.5-grams

Water: 7000-grams

Please note that all of these do not align with your numbers based on 12500-grams of flour weight.

[Re: Dough not rising and too white](#)**323**

It appears that the dough box might be too big for the size and count of the dough balls that you are using.

[Re: Dough balls drying out on wooden boxes](#)**324**

Just for the record, I'm not a big fan of composite peels, they tend to be overly heavy for their size and the dough tends to stick to them. I'll take a good wood peel every time.

[Re: Transferring From peel to the stone has been my biggest problem](#)**325**

High dough absorption, well fermented dough baked at 850F+ and hand formed.

[Re: Canotto style](#)**326**

Using your spiral mixer I really think you can just add all of the ingredients to the mixer at the same time (including the poolish) and begin mixing, this will result in better mixing action which will result in a shorter mixing time. Use cold water (at least 60F) and shoot for a finished dough temperature of 75 to 80F. Regarding the 15-minute cross-stack time, this is not nearly enough time to accomplish anything, instead allow the dough balls to remain cross stacked until the internal dough ball

temperature reaches 50 or 55F (pick one), then down-stack and kiss the dough good night. Note: Be sure to lightly oil the top of the dough balls to prevent excessive drying of the dough during the cross-stack period.

[Re: Neapolitan dough in a spiral mixer](#)**327**

I don't know how much you are referring to when you say that your dough "shrinks back" when peeling the dough into the oven but there are two things than can be done, one is to ensure the dough has been properly fermented (insufficiently fermented dough has a greater tendency to exhibit memory characteristics) and to open the dough up to a slightly larger diameter than what you are targeting with the knowledge that the dough will shrink back to the target diameter as you peel it into the oven. Additionally, during the baking process you can expect the pizza to contract by something between 1/4 and 1/2-inch in diameter.

Other things which can/will impact the way the dough handles on the peel:

Dough temperature (warm dough tends to be more problematic)

How thin the skin is (very thin skins are more problematic)

Amount and viscosity of the sauce used. (heavy sauce application and thin sauce viscosity tend to be more problematic)

Length of time needed to assemble/dress the pizza/skin. The longer it takes the greater the propensity for the dough to stick)

Type of peel being used. (In my experience wood peels are easier to use and more forgiving)

Failure to shake the skin on the peel during and after building the pizza can result in the dough sticking to the peel.

Just some ideas for consideration.

[Re: Transferring From peel to the stone has been my biggest problem](#)**328**

We just returned from vacation in Park Rapids, Minnesota and while we were there we visited Linda's Recycled Goods, 807 West 1st. Street, Park Rapids MN. 56470/ Tel: 218-252-3949/ Cell: 218-252-5005/ Linda and Richard Anderson (owners). In their back room they have a lot of different size deep-dish pizza pans. I bought a dozen individual size deep dish pans for just \$2.00 each. The pans range in condition from very good to like new. If any of our members in Minnesota are located close to Park Rapids and you are interested in getting some (what appear to be Pizza Hut) individual size deep-dish pans, this is a good opportunity pick some up and look at other pans which they also have.

[Deep-Dish Pizza Pans](#)**329**

92F is much too hot for your dough. What was the temperature of the water that you were using to make the dough with? Also, please tell us about the formulation, age and amount of poolish you used.

[Re: Neapolitan dough in a spiral mixer](#)**330**

Since N.Y style pizzas are typically baked at a lower temperature than NP style pizzas you could bake the NP pizzas first and then bake the N.Y. style pizzas in the cooler oven.

As for the water question, Soft water is not preferred for making dough and R.O water is even less preferred. This is because of the beneficial effects of the minerals in hard water on the dough and fermentation. If you do a search through the archives you will find quite a bit of discussion on hard v/s soft water in making dough.

You also mention multi-grain and whole-grain doughs, again, we had some excellent discussion on that topic not too long ago where I gave the procedure for

finding the correct dough absorption and dough making process for there sometimes difficult to make doughs. Done correctly they will make great pizzas but done incorrectly whole-grain and multi-grain pizzas are many time described with words like cardboard, leaves and twigs, etc.

If you are planning to use your wine room as opposed to a refrigerator for cold fermentation you will need to reduce the yeast amount and you may not get the same flavor profile in the finished crusts as you would at the lower temperatures.

[Re: low or high hydration whats the advantage of both ?331](#)

The amount of "old" dough that can be added is highly variable depending upon the formulation and age of the old dough so the amount added will be application specific. When we studied this many years ago we found that, for the most part, we could add 15% (based on the total fresh dough weight) old dough without significantly impacting the performance of the new dough, so in your case the amount added will be something greater than 15%. I would suggest starting with 20% old dough addition and going up in 10% increments (30%, 40%, 50%, etc.) from there. Because the amount of old dough is being calculated on a "true %" basis (based on total dough weight as opposed to bakers percent) no other dough changes are generally needed. The end result is similar to that of using a biga or a "sponge" in making a dough.

[Re: how much old dough in % for 1 kg flour new dough batch ?332](#)

Not knowing anything about the strength of your sourdough starter, I'd start at 5% and go up in 5% increments. For a "true" sourdough no yeast is used, plus typically a sourdough doesn't play well at refrigerated temperatures so you might want to think about 12 or 24-hours at room temperature for starters.

[Re: Please help me troubleshoot my Neo pizzas from tonight333](#)

If using compressed yeast use 1%.

No change in water temperature is needed.

When I'm making N.Y. style pizza at home I like to use All Trumps Flour (14+% protein content).

[Re: Dough recipe using Caputo Americana flour334](#)

Use a little flour or oil on your hands to remove the dough from the bowl, then use a plastic bowl scraper to scrape the dough up for the folding process, after a few folds it will become noticeably easier to manage, don't be afraid to use a little dusting flour too to help get things started. Remember, you're making dough, not rocket fuel or nitro glycerin ;D

[Re: A real noob question: sticky dough335](#)

Different types of pizzas have different identifying characteristics and water/dough absorption is a tool that we use to achieve some of those characteristics. Higher absorption = a softer, more fluid dough that will exhibit more oven spring during the baking process while lower absorption will tend to inhibit oven spring. I'm not sure if all of this is covered in the function of ingredients that we have here but do take a look. We're always happy to expand on any questions which you might have.

[Re: low or high hydration whats the advantage of both ?336](#)

Yeast is NOT an oxygen scavenger, it produces carbon dioxide during fermentation which will displace a small portion of the oxygen/air in the dough. In an anaerobic environment ascorbic acid is indeed a dough reducer but to get the reducing effect you need to mix the dough under a vaccum using a Tweedy mixer. Forget what you

read as it does not apply here. Just go ahead and make your dough as you normally do.

[Re: iced water for flour with ascorbic acid](#)337

What was the flour weight in your dough formula, need it to determine the IDY percentage.

[Re: Please help me troubleshoot my Neo pizzas from tonight](#)338

Agreed. I do see at the 2 o-clock position, slightly in from the edge an area of dough collapse resulting from insufficient bake time.

Next time try par-baking the crusts with 1/2 of the sauce on them and you will get a better finished crust.

[Re: Why does my skin look like this?](#)339

What you are looking at is a pasta flour made from a variety of durum wheat, not the best choice for making pizza. The gluten that is formed from durum flour is vastly different (it has little extensibility) from that of wheat flour.

[Re: Want to try a new flour](#) 340

His two favorite words: You're fired!!! I didn't include the common adjectives he included with the phrase for obvious reasons.

Sorry Donald, he beat you to the phrase. :-D

[Re: Fried pizza dough](#)341

Yep, 3-hours RT fermentation is just OK for bread but it sure doesn't cut it for pizza. Reduce the IDY to 0.4% and CF for at least 48-hours. I've posted my Dough Management Procedure here a number of times if you need a procedure to start with (a quick trip through the archives will bring it up). I would do this with my regular flour first, and then begin introducing other flours in 10% replacement increments up to 30%. This will allow you to assess the many different options across their typical use level and hopefully find something that you like while having fun experimenting at the same time. Just remember to keep good records (times and temperatures are important to record in your notes).

[Re: What flour should I try next? Looking for a certain taste](#) 342

Do the crusts look normal immediately when coming out of the oven? If so the issue is due to collapse resulting from insufficient bake.

[Re: Can anyone help me figure out this issue](#)343

I was working for him at one time, once was enough!!!

[Re: Fried pizza dough](#)344

One other thing, vacuum packaging is NOT recommended for dough or finished product due to the potential for clostridium. MAP is what everyone uses.

[Re: Looking to make frozen dough](#)345

No, a yeast spike is added AFTER the poolish, the idea is to have some yeast in the dough that has not been allowed to ferment (it will have a better survival than yeast that has been allowed to ferment). Even the best frozen dough manufacturers only get 21 to 23-weeks of frozen shelf life from their dough. To get that kind of shelf life you will need to blast freeze the dough at -30 to -37F with 600 to 800-linear feet of airflow over the product, or you will need to use a cryogenic freezer (liquid nitrogen or carbon dioxide) with pressure adjusted to give a temperature in

the product zone of -50 to -65F, then package and immediately place into a holding freezer at -15F to finish freezing. After 2-hours in the holding freezer the internal dough ball/puck temperature is measured, if it is -15F the time in the cryogenic freezer is correct, if the temperature is higher than -15F the time in the cryogenic freezer will need to be extended and if the temperature is lower than -15F the time in the cryogenic freezer will need to be reduced (as a matter of economics). Date loggers are placed with shipments of frozen dough to monitor dough temperature (temperature abuse is a major cause of dough failure) during distribution.

[Re: Looking to make frozen dough](#)**346**

The question that begs to be asked is, what does your "tasteless" crust dough formula look like?

[Re: What flour should I try next? Looking for a certain taste](#)**347**

Don't forget that the Celeste brand frozen pizza is made using a fried crust, it was the topic of a huge and long running legal law suit between Pillsbury and Jeno Palucci which finally ended in 1985 when Jeno sold out to Pillsbury. At one time it was estimated that legal expenses were about 10-million dollars a year for that suit and anyone even thinking of frying a piece of dough was targeted in the suit too.

[Re: Fried pizza dough](#)**348**

I like all three, but my preference is for the Marsal oven, thicker decking and lots of BTU's make for great ability to continually load and unload pizzas without any difference in bake. Just don't buy into the story line about not needing to rotate the pizzas in the oven, I've never found that to be true for any deck oven with a door! NOTE: Their gas decks come with an internal gas regulator already installed, DO NOT install another gas regulator.

[Re: Marsal vs. Blodgett vs. Bakers Pride Gas Ovens](#)**349**

There are thin crispy pizzas and there are cracker type pizzas. What you appear to be looking for is a thin crispy type aka Chicago style thin crust pizza. You really don't need to go very far back into the archives here to find discussion and some very good pictures of this type of pizza.

[Re: Chicago Thin \(Cracker?\) Crust Pizza/ Bar Pizza](#)**350**

Boy! It would sure be nice to be able to see your dough formulation as well as your dough management procedure on this one, inconsistency with the dough is really hard to nail down without knowing exactly what you are doing. Remember, T.M.I. is not an issue so be sure to include all times and temperatures when outlining your dough management procedure.

[Re: Consistency, hydration and oven temp](#)**351**

An Edge oven would be a very good place to begin looking at an oven to bake your heavily laden pizzas. Air impingement ovens are, by far, the best suited ovens to bake that kind of pizza. Your dough formula looks to be pretty typical so I see no issues there. You can get any kind of bake you want from an air impingement oven BUT the oven MUST have the finger profile properly configured for YOUR specific product. Edge has always been good at working with their customers to make sure the oven they are buying is properly profiled so work with them, to get the bake you want. Additionally, there are a host of different baking platforms for use in air impingement ovens so if you don't get the bake you want on one platform be sure to try some of the others. NOTE: In case you're wondering, a "baking platform" is a

screen, pan or disk used to carry the pizza through the oven. Just make sure whatever you use is either seasoned to a dark color or has a black/dark gray anodized finish.

In the event that you are not satisfied with the air impingement oven there are always conveyor deck ovens to be considered, they are significantly more expensive, but they are a viable option.

[Re: Pizzeria Needing Wisdom!](#)**352**

If you can live with a maximum frozen shelf life of 15-days what you are proposing doing is totally feasible (assuming you are going to be freezing the dough in a static freezer). Why only 15-days? It has been well documented that yeast which has been subjected to any amount of fermentation does not fare well when frozen in any kind of freezer, much less a static freezer (-10 to 0F with little to no airflow), this results in the potential for significant yeast damage as a result of being frozen which, in turn, leads to dough failure. We do know that the dough will perform reasonably well out to about 15-days but after that it's a crap shoot as to whether it will perform to customer's expectations or not and when we are selling dough you have to remember that FAILURE IS NOT AN OPTION. I would recommend using a yeast spike in the dough (addition of 0.2% IDY when making the dough) then mix the dough as cold as possible (under 70F if at all possible) then immediately go to scaling and balling. Allow the dough balls to rest for 5-minutes then flatten into "pucks" about 1 to 1.5-inches thick, lightly oil, place on aluminum sheet pans that have been stored in the cooler, place the dough pucks on the sheet pans and immediately take to the freezer, freeze uncovered for at least 3-hours, then while in the freezer, package the dough pucks in plastic bread type bags (1.5-mil. thickness) being sure to pull the bag snug to the dough puck, twist the open end into a pony tail and apply a twist tie close to the dough puck, place the pony tail under the puck as you package the dough for sale. Note: This is all done in the freezer to prevent condensation from forming on the dough.

[Re: Looking to make frozen dough](#)**353**

Well...it all depends upon what you mean by "better". You can add non-deodorized lard for a different flavor, and I like to use bacon "drippings" for a different flavor too. A lot of people like to use Butter Flavored Crisco or Blue Bonnet Margarine (Chicago) but that's still a butter flavor.

[Re: Cracker style dough](#)**354**

Two things I'd do, increase the dough absorption to at least 68% (possibly more) and decrease the individual dough ball weight to achieve a dough loading of 0.079646-ounces per square inch of surface area for the skin size you are opening the dough to. If you want to continue using the same dough absorption and dough weight you will need to drop the baking temperature to 500F.

[Re: Where did the crust go? Air bubble...](#)**355**

Generally, an AP flour works well in this application. (10.5 to 11.2% protein content)

[Re: Cracker style dough](#)**356**

What I'm seeing is a dense crumb structure with the top crust lifted away from the crumb portion. Do the actual slices reflect that observation?

[Re: Where did the crust go? Air bubble...](#)**357**

Are you saying the dough was "cold fermented" at 61F?

[Re: Where did the crust go? Air bubble...358](#)

It appears that the crust might have been baked at too high of a temperature for the weight of the skin but to cover more bases, please tell us about your dough management procedure (everything you do with/to the dough from the time its mixed until you open the dough into a skin and dress it for baking).

[Re: Where did the crust go? Air bubble...359](#)

You would want to use 0.5% ADY to replace the 0.375% IDY. Don't forget to suspend the ADY in a small portion of the dough water adjusted to 95-100F and allow it to activate for 10-minutes before adding it to the dough water in the mixing bowl. If using the commercial dough boxes: scale, ball, place dough balls into dough box, lightly oil the top of each dough ball, place in cooler (UNCOVERED) until the internal dough ball temperature reaches 50F, then lid the box. Note: The dough must be scaled, balled boxed and in the cooler within 20-minutes of removing the dough from the mixer. The dough should be cold fermented for a minimum of 24 hours (48-hours is better). To use the dough, remove from the cooler (leave the box lidded) and allow the dough to temper AT (NOT TO) room temperature until the internal dough ball temperature reaches 50F, the dough is then ready to begin opening into skins for immediate use. The dough balls will remain good to use for up to 2,5 to 3-hours, just remember to KEEP THE BOX LIDDED after removing a dough ball.

[Re: Dough recipe using Caputo Americana flour360](#)

What the picture shows is a thin crust skin which was formed on a sheet and die cut production line. Typically the dough has a moderate dough absorption of about 56%, it is NOT fermented, but instead used a reducing agent such as dead yeast (RS-190) or L-cysteine (PZ-44) to achieve the necessary extensibility for efficient processing. After mixing to a smooth, cohesive dough consistency (75F) the dough is taken to the automated sheeting line where it is deposited onto the production line and then reduced to approximately 3/16-inch in thickness by means of a series of reduction rolls or more likely than not, a cross roller, a single reduction roll and then a satellite multi-roller reduction roll followed by a single gauge roll then a docking roller and a die cutter. After that it's off to a blast freezer where it is frozen to +15F in about 20-minutes, then it exits into a temperature and humidity controlled room for packaging, bulk packing, palleting pallet wrapping and into a holding freezer (-10 to -15F) for 18 to 24-hours prior to shipping to a distributor.

Wanna make it at home?

Flour: 100% (12 to 12.8% protein content)

Salt: 2%

Sugar: 2%

IDY: 0.6%

Oil: 2%

PZ-44: 2%

Water: 56% (variable)

Procedure:

Mix to a smooth, cohesive dough consistency.

Scale

Ball

Allow to rest at room temperature for 10-minutes.

Roll out to 3/16-inch in thickness.

Dock the dough.

Place the dough on a 12" diameter pizza screen and trim off excess dough.

Leave the dough on the screen and place in a freezer for 1-hour.

Transfer the frozen skin to a pizza circle and wrap for frozen storage (will keep for up to 15-days).

[Re: frozen pizza crust](#)**361**

As a general rule, make no other changes, just reduce or eliminate the sugar, if you still want/need more bake time after that reduce the oven temperature slightly (15 to 25F). This will allow more time for the top of the pizza to finish baking while reducing bottom bake color.

[Re: Gas fired brick oven dough recipe question](#)**362**

I agree ^^^

A thin crust is one thing and usually not much of an issue but my reference was for a thick, scaly crust (bad enough that you might be able to strike a match on) and usually only occurs when the dough was not covered for an extended period of time. I suppose if one was at high altitude or in a dry desert environment you could achieve the type of crust I was referring to in less time? But I too would question only 2-hours.

[Re: Forgot to oil my dough balls - question](#)**363**

In most all pizzerias the dough is just mixed until it's smooth, the dough is then scaled, balled and placed into dough boxes for cold fermentation. Cross-stacked about 2-hours (50 to 55F) internal dough ball temperature, then down-stacked and kissed good night. On the following day the dough is removed from the cooler and allowed to warm to 50F (internal dough ball temperature) before opening into skins. The dough is good to use for about a 3-hour period by this method.

No other handling of the dough is required. There is a huge difference between a K5A and a 60 or 80-quart commercial planetary mixer.

If you go to my web site <doughdoctor.com> you will be able to watch my dough making video to see how a pizzeria makes their dough.

[Re: gluten development. small batch vs large batch](#)**364**

Dry, crusted dough is insoluble in the dough. You will most likely be reminded of it again when you go to open the dough balls into skins. How bad it will be remains to be seen.

[Re: Forgot to oil my dough balls - question](#)**365**

Here is my N.Y. Dough formulation.

Flour: 100%

Salt: 1.75%

Oil: 2%

IDY: 0.375%

Water: 63% (variable) / (60F)

Targeted finished dough temperature: 75 to 80F

Mix Just until the dough becomes smooth.

Scale and ball.

Lightly oil dough ball.

Place in plastic bread type bag, twist open end into a pony tail and tuck under the dough ball as you place it in the fridge.

Cold ferment 24 to 48-hours (48-is better).

Remove from fridge and allow dough ball to warm to 55F internal temperature, then turn out of the bag onto a flour dusted surface.

Open into a pizza skin by your preferred method.

Dress and bake on a stone or steel.

[Re: Dough recipe using Caputo Americana flour](#)**366**

There should be no need to add any additional malt just for the durum semolina flour as "hopefully" you are not planning to use it at 100%. Ideally, it should not be used at more than 25% of the total flour (3-parts regular flour + 1- part durum semolina flour). That is unless you want the finished crust to go in direct competition with the likes of Good Year, Firestone, Uniroyal, Cooper and a host of other tire manufacturers....it'll be that tough and chewy soon after baking.

[Re: Extra fancy durum flour add diastatic malt?](#)**367**

Be sure to avail yourself of the services and guidance available from the Think Tank at <www.pmq.com>, the TT is visited mostly by operators.

[Re: Opening up a pizza shop.](#)**368**

A different/unique flavor that can only be achieved through the use of a sourdough starter that has been properly managed, which is a whole 'nother story.

[Re: Predough and timing questions](#)**369**

Enzymes are used at very low levels but the flour still functions as a malted flour.

[Re: How to know if flour is malted? This one?](#)**370**

Ricko;

The answer is ABSOLUTELY,POSITIVELY YES! That is unless you have a favorite beneficiary on your life insurance policy that you would like to toss a few bucks their way. Clostridium is nothing to mess with, it's DEADLY, and it doesn't take much to accomplish the evil deed.

[Re: Growing Your Own Tomatoes](#)**371**

As a "newbie" Which I assume you are, I would encourage you to begin your pizza making endeavors using a more traditional flour for your first pizza making excursions. Something like Pillsbury Bread/Bread Maker Flour or KABF would be a good starting point, these flours are quite forgiving and will allow you to better develop your skills while building your confidence, then in a short time you can transition to your Caputo flour.

Just a suggestion.

[Re: Just got my caputo blue pizzeria flour, need help with fool proof recipe ooni](#)
372

A lot will depend upon the environment in which you are proofing the dough and for how long. When you open the dough into relatively flat circle you significantly reduce the cross section dimension while at the same time increasing the surface area, both of which will allow the dough to be more responsive to (influenced by) the temperature in which it is placed so if the dough is 85F as a ball and the room is 70F the ball will retain its temperature much better than the opened dough which will quickly cool to the 70F room temperature and since temperature is the number one driver of fermentation the lower temperature will result in a slower rate of fermentation. If several hours are involved there is also heat of metabolism that has to be considered too. As the dough ferments it will warm due to heat of

metabolism from the yeast feeding. This will warm the dough at the rate of approximately 1F per hour. The flattened dough piece will also experience this same heating BUT due to the reduced cross section and greater surface area it is much less able to retain this heat so its impact upon the rate of fermentation is significantly lessened.

[Re: Does the dough shape impact how fast the dough rises?373](#)

If you are re-ballng the dough just 1.5-hours prior to opening the dough into a skin I'm betting that you are also experiencing issues with opening the dough too? You should find that the dough opens easiest when you just remove it from the fermentation container and drop it into some dusting flour and immediately proceed to begin opening the dough.

By the way, after removing the dough ball from the fridge you only need to allow it to warm AT (not to) room temperature until the internal dough ball temperature reaches the 50 to 60F/9.9 to 15.5C range. Depending upon your proficiency at opening the dough you may find it easier to open the dough at the cooler side of the temperature range.

[Re: Not "breaking" the fermentation bubbles ?374](#)

There can be, but any issues are essentially eliminated by lightly oiling the top of each dough ball as it is placed into the box and effectively cross-stacking (leaving uncovered) until the internal dough ball temperature reaches 50F before down-stacking/lidding the box(es).

[Re: Best height for dough trays?375](#)

Some of the Lloyd's disks are not intended for use in any type of deck oven. Only those that are fully perforated across their entire diameter will work in a deck oven without warping. The others are intended for use in air impingement ovens.

When going to the 16" diameter pizzas you might try reducing the dough absorption in 2% increments until you find that you can easily work with the dough without it sticking, then, as you gain confidence and proficiency begin gradually increasing the dough absorption. Remember, that dough absorption is ALWAYS going to be somewhat of a variable since it is tied to the absorption properties of the flour which is variable/not consistent.

[Re: Can you use a pan to bake a NY style in Blackstone?376](#)

Another thing to consider is the dough weight (assuming no sugar in the dough formulation). If the skin is too thin/light weight for the diameter you will have a harder time getting to bottom to bake properly than if you have a slightly greater dough weight. The next time you make pizzas make a couple of dough balls 1-ounce heavier and a couple 2-ounces heavier (open them all to the same diameter) bake the pizzas to desired bottom color.

[Re: Newbie help with crust 'doneness' in a brick oven377](#)

It ain't necessarily what you've got that counts, it's what you do with it that matters most, so you have the dough formula, as well as the flour down pat, the question now is how are you managing the dough (that's where the "rubber meets the road"). You can use the same dough formula but manage it differently and get different finished product characteristics. Please be specific as TMI is seldom an issue here just so long as it's pertinent to the topic. ;D

[Re: How do you get a crust like this? 378](#)

You might also try leaving the cover off of the container until the dough reaches

50F, then covering. This will allow the dough to be more tolerant to variations in finished dough temperature as well as slight differences in refrigeration temperature thus diminishing the likely hood developing an over fermented dough condition. This approach has been discussed any number of times here where it is referred to as "cross-stacking and down-stacking".

[Re: Bottom of dough](#) **379**

Forgot to add one more thing, how tight or loose you're rounding the dough balls.

[Re: Best height for dough trays?](#) **380**

Your Caputo Americana flour, if I remember correctly comes in around the high 12% protein content range and is already malted so you shouldn't have any problems baking at 550F. Every flour will exhibit different dough absorption properties so I would suggest starting out at 60% and adjusting up or down from there if necessary.

[Re: Just bought some Caputo 00 Americana. Do you guys adjust hydration by flour?](#) **1**

As a rule:

The more flour there is in the biga the softer and more extensible the dough will be, this in turn promotes a larger, more open crumb structure.

As for the amount of yeast used in a biga we found best results when the % of yeast in the biga was the same as used in the dough BUT remember that the amount of yeast in the biga is based ONLY on the weight of flour in the biga. You then calculate the weight of yeast based on the yeast percent and the TOTAL flour weight then subtract the weight of yeast used in the biga, the remainder is the weight of yeast that goes into the dough side. If the biga is to be fermented overnight the amount of yeast as compressed yeast or its equivalent in ADY or IDY should not exceed 0.25%, this yeast is not considered as part of the total yeast.

[Re: BIGA - Flour and Yeast Amounts](#) **2**

I haven't priced them recently but typically the Marsal ovens are cheaper than the rest of the lot. Make sure you're comparing equal size ovens.

[Re: Temperature of Pizzeria Oven](#) **3**

Aside from the finished/mixed dough temperature please tell us all you can about the flour you're using.

[Re: Problem with overfermenting](#) **4**

It'll be hard to go wrong with a Marsal gas fired deck oven. Your baking temperature will most likely fall somewhere in the 500 to 550F range. When locating the oven be sure to allow at least 1.5 times the depth of the oven as free space in front of the oven for the oven tender to work in.

[Re: Temperature of Pizzeria Oven](#) **5**

That's the procedure but since then I've added the following:

The dough should remain cross stacked until the INTERNAL dough ball temperature reaches 50F/10C. NOTE: The time required for the dough ball to reach this temperature will change with the size/weight of the dough ball, so each dough ball weight will require a different time. Once you have determined the correct time for each dough ball weight you can then go by the time required to reach 50F/10C and use that for your cross-stack time for that dough ball weight.

After the CF (cold fermentation) period, remove the number of boxes of dough balls that will be required for the first three hours of operation, place the dough boxes AT room temperature (70 to 80F/21 to 26.6C) to allow the dough balls to warm TO 50F/10C INTERNAL DOUGH BALL TEMPERATURE. DO NOT ALLOW DOUGH BALLS TO WARM TO ROOM TEMPERATURE!!

Once the dough balls have warmed to the targeted temperature they are ready to begin opening into skins for immediate use. The dough balls will remain good to use for the next 2.5 to 3-hours. NOTE: If your shop is warmer than 80F/26.6C this time will be reduced and you will need to take this into account when determining how many dough boxes to remove from the cooler and at what frequency to remove them during the day.

Any dough balls nearing their expiration time at room temperature can be pre-opened, placed onto screens and stored in a wire tree rack in the cooler for use during the next busy rush period. After placing the pre-opened skins into the wire tree rack in the cooler leave the rack uncovered for 30-minutes, then cover with a plastic bag to prevent drying. To use the pre-opened skins, remove from the screen, touch up the size as needed, place onto wood prep-peel for dressing and immediate baking. If baking on screens BE SURE TO TRANSFER THE SKIN FROM THE STORAGE SCREEN TO A SEASONED BAKING SCREEN. DO NOT BAKE ON THE STORAGE SCREEN EVEN IF IT HAS BEEN SEASONED WITHOUT LIFTING IT OFF OF THE SCREEN FIRST AND THEN PLACING IT BACK ONTO THE SCREEN. FAILURE TO DO THIS WILL RESULT IN THE DOUGH BAKING INTO THE SCREEN MAKING REMOVAL FROM THE SCREEN IMPOSSIBLE WITHOUT DESTROYING THE BAKED PIZZA.

[Re: Pizza Dough Storage & Handling Questions 6](#)

I don't know if Peter has my Dough Management Procedure posted here but if he doesn't PM me with your email address and I'll be glad to send you a copy of it which will lead you through the entire process from mixer to getting ready to open the dough balls.

[Re: Pizza Dough Storage & Handling Questions 7](#)

Larger cell structure which promotes greater fat absorption during frying. As a general rule your donuts should weigh about the same after frying as they did before going into the fryer, if they weigh more you most likely are experiencing excessive fat absorption.

[Re: on fat : oil, margarine, vegetable shortening, butter 8](#)

To be a little more precise, we've found that in most cases, for a same day preferment, it's best to use the same percent yeast in the preferment as you use in the dough BUT remember that the amount of yeast in the preferment is based only on the amount of flour in the preferment. This amount of yeast is then subtracted from the total amount of yeast (based on the total formula flour). When an overnight preferment is used we found best results using 0.25% yeast (as compressed yeast/CY) or its equivalent in ADY or IDY. In this case the amount of yeast used in the preferment is NOT included in the total yeast amount.

[Re: Quantity of yeast in a preferment after calculating total weight of ingredients 9](#)

I really can't tell much from the poor quality picture as it's all washed out. The fat flakes will be visible in the dough at the end of the mixing process, if they aren't they won't perform in the manner expected. After mixing allow the dough to rest for about 15-minutes, then sheet out to about 3/16-inch in thickness using a rolling pin or pastry pin. then follow directions provided in my original post.

If you want to read up on a similar process study the "Blitz" method for making Danish Pastry or puff pastry, or even pie dough for that matter, they're all very similar.

[Re: Pizza Pockets 10](#)

What you were missing was the temperature of the bench top. By hand kneading you were exposing a great amount of the dough surface to the bench top which now most likely had a significant impact upon the dough to lower the temperature to something closer to the measured room temperature.

[Re: Friction Factor and Final Dough Temperature 11](#)

All Trumps? The single most popular flour used in NYC. It comes in at 14 to 14.5% protein content.

[Re: New Park Pizza Dough... Flour Used? 12](#)

nhnybo;

Do you cover/lid the fermentation containers when you put them into the fridge? Keep in mind that by putting the dough into the fridge/cooler the yeast doesn't immediately slow down, there is a significant cooling curve before the core of the dough ball reaches a temperature that will inhibit yeast activity. Part of this long curve is due to the heat being generated by the yeast as a result of heat of metabolism which can amount to a temperature rise of 1F per hour, so we're removing both the latent heat in the dough plus the heat being generated by the yeast as it feeds. A tool that we commonly use is to adjust the finished dough temperature. With a higher temperature there will be a longer period where the dough is in the temperature range which will support fermentation and a lower finished dough temperature means that the dough will be in this temperature range for a shorter period of time. For example, if we plan on a 7-day CF period we would target a lower finished dough temperature so there is less up front dough fermentation which means the dough won't be suitably conditioned for use at 24 or maybe even 48-hours but it will be ready to go on the 5th day after mixing and will remain good to use through the 7th day. Conversely, if we target a higher finished dough temperature the dough can be easily made to be ready to use after 24-hours CF and still provide decent results out to 48 and possibly 72-hours, but it's a pretty sure bet that it won't be in its prime out at 7-days. This highlights one of the main reasons why I don't advocate allowing the dough to ferment prior to CF. The dough becomes less dense with fermentation so it is becoming harder to cool and extract the heat being generated by the yeast. This is what leads to inconsistency in the rate of cooling the dough balls and when this happens the inconsistency will result in inconsistent dough performance or even failure several days down the road.

This is also why we highly recommend that the initial cooling of the dough (to 10C) be done with the dough box uncovered, this allows heat to freely escape, prevents condensation from forming inside of the dough box and doesn't create a dead airspace around the dough balls in the box which is just another insulating factor that will inhibit cooling the dough balls at a consistent rate.

As I used to express to my students all the time, the most important factors in making good dough (for any kind of product) are temperature control (without temperature control you cannot have effective dough management) and consistency, whatever you make, if you cannot make it consistently the same all the time, at the end of the day you still don't have anything.

[Re: Guaging Fermentation 13](#)

What most people associate with a "yeasty" flavor isn't yeast at all, instead it's the

by-products of fermentation that is providing that flavor. Yeast has a flavor that might best be described as somewhat like that of old, wet newspapers, after all, it's a member of the mold family. So, to your question, with IDY or any other type of yeast you will just want to avoid over fermenting the dough. Typical for yeast raised donuts is mix, (75 to 80F) bulk ferment 1-hour, cut into manageable size pieces and form into loaves, allow loaves the ferment for 30-minutes (approx), sheet to 1/2-inch thickness, cut, place on proofing screens, proof at 80 to 85F (90F max.) for about 45-minutes, fry at 365F.

Think of this: a very rich sweet dough will contain over 20% sugar, and about as much fat, the yeast level will be about 4.5% IDY and there is no "yeasty" flavor because the fermentation time is very limited. By the way, the definition of a yeast raised donut dough is a very lean sweet dough.

[Re: on fat : oil, margarine, vegetable shortening, butter](#)14

As Peter and many of the community here know, my first experience with pizza was with the Chef Boyardee pizza mix which is really not much more than a glorified biscuit dough mix. Whatever the case, it worked to get me hooked on pizza for life!
:-D

[Re: Instant Dough](#) 15

The whole point of an emergency dough is to produce a dough which is suitable for making "pizza" (and I do mean "pizza" very generically), within a very short time after mixing. The ingredient amounts are changed as is the dough temperature with the specific intent to give a dough that can be formed into skins for making pizza in as short a time as possible. My own personal best is 30-minutes after mixing we were opening the dough balls into skins and dressing them for baking. Some might equate this to "S-O-S" but it still looked like a pizza so that's what we're calling it. ;D

[Re: Guaging Fermentation](#) 16

It does need to be pretty well developed but not as much as for making bread. Two hours final proofing time for a yeast raised donut is insane! WWAAYY too long! Try increasing the yeast to get the final proofing time down to about 45-minutes. That will help with the size too and most likely reduce fat absorption at the same time.

[Re: on fat : oil, margarine, vegetable shortening, butter](#)17

Sure, not the best but still "pizza" none the less.

Caputo Americana flour: 100%

IDY: 1%

Oil: 1%

Salt: 2.5%

PZ-44 or RS-190 (dead yeast): 2% (variable)

Inactive dry white sour: 2% (variable)

These will be the ingredients you will want to work with, really not much of a challenge to do it.

[Re: Instant Dough](#) 18

Welcome to the club! :)

To get some background on deep-dish pizzas spend a little time looking at past discussions on deep-dish pizza, it'll provide a good primer for you to begin journey to making some great pizzas. A couple of things that you will want to have to begin with are an inexpensive scale for weighing ingredients, a dark colored deep-dish pan 1 to 1.5-inches deep and 10 to 14-inches in diameter and a metal blade cake

decorating spatula for use in removing the pizza from the pan. If you have any questions about your ingredients just let us know, there are plenty of us here to help you.

[Re: deep dish pizza](#) **19**

How long are you final proofing the donuts? Can you provide a picture of the proofed donuts just before going into the fryer?

[Re: on fat : oil, margarine, vegetable shortening, butter](#) **20**

Your question is impossible to answer without knowing more about your dough balls. As a rule, we use up to 10-ounces in the 3" depth, 11 to 14-ounces in the 4" depth and anything over 14-ounces in the 6" depth. Keep in mind though that dough balls will rise differently in the box depending upon dough temperature, how well you're managing your dough, yeast level and dough absorption.

[Re: Best height for dough trays?](#) **381**

Agreed, a N.Y. style dough formula:

Flour: 100% (12.2 to 12.8% protein content/strong bread type flour)

Salt: 2%

Sugar: 1%

Oil: 2%

IDY: 0.375%

Water: 65%/variable (65F)

Mix/scale & ball/cross-stack to 50F/down-stack/CF for 48-hours/remove from cooler and allow to warm to 55F internal ball temperature/open into skins by hand/dress/bake at 700F.

This should provide you with a starting point for achieving your goal.

[Re: How do you get a crust like this?](#) **382**

Remember, there's a learning experience in every mistake.

[Re: Cold Fermenting Overproofed Dough?](#) **383**

It's nothing to worry about.

[Re: Measuring internal temp without Degassing?](#) **384**

Not knowing what your dough formula is I cannot say if adding sugar will impart a sweet taste to the crust, but keep this in mind; you will not get a detectable sweet taste in the finished crust until the sugar (sucrose) level is 4% or more. With that said, the addition of sugar will result in the entire crust developing more color and at a faster rate on both the top and the bottom. The problem you're experiencing is most likely due to the high crown in your grill which does not provide sufficient top heat directly to the pizza as it's baking. An application of oil to the top of the dough not covered by the toppings might help a bit. You might also try brushing it with whole milk too.

[Re: Oil or Sugar for more Crust Browning on Top?](#) **385**

Mine is a very high priced cake pan with a plastic lid that I got at a very exclusive store called Walmart. I have about 2-cups of my dusting flour in the pan and I so do all of the dough ball dusting in/over the pan (makes less of a mess), when I'm finished I just snap the lid back on the pan and put it away until the next time I need it.

[Re: Bowl of flour used to open dough balls](#) **386**

What you propose should work OK, just remember that whole-wheat flour has a higher absorption than your regular white flour (about 70% in most cases) and like semolina flour it is slower to hydrate than white flour. This means that in this case an autolyze/soaker might be of benefit as it will allow time for the whole-wheat and semolina flour to properly hydrate. Just in case you're wondering, the whole-wheat flour is slow to hydrate due to the presence of bran particles in the flour and the semolina flour is slow to hydrate due to its large particle size. Additionally, semolina flour can be made from hard wheat varieties or it can be made from durum wheat varieties, it's important to know what it was made from as if it was made from a durum variety you might want to limit its use to something under 25% of the total flour blend. It will contribute to crispiness but it will also contribute to toughness aka chewiness in the finished crust as it cools.

[Re: Semolina and whole wheat flour in formula](#)387

Sure, not a problem saving it. If you were to ask 20 people what they use for a dusting flour you would probably get a minimum of 25 answers :-D there are that many different opinions. Wheat flour, rice flour, corn flour, fine corn meal, semolina flour and wheat bran are all used both alone and in various combinations. My own personal favorites are fine corn meal as well as a blend of equal parts fine corn meal + semolina flour + regular white flour.

[Re: Bowl of flour used to open dough balls](#)388

If you do a quick search you should find some of the previous discussions we've had here on the topic, there is actually quite a bit to bulk fermenting prior to balling.

[Re: Advantage of Bulk or not to bulk](#)389

Looks GREAT!!!! :chef:

I also like to add some shredded Parmesan cheese to it too, but that's just me.

[Re: Had 'no knead' dough in fridge, turned it into focaccia](#)390

Depending upon the flour strength, amount of yeast used, proficiency at temperature control I would, with trepidation, say yes for home pizza making only. Try to keep the time the dough is frozen as short as possible. Keep in mind that you may need to be re-ballining the dough at some point.

[Re: Reversing cold fermentation](#)391

A little bit but not all that bad for the flour you're using. I would recommend reducing the total dough absorption to 62%. Remember that dough absorption is ALWAYS variable, especially with "00" flours.

[Re: Dough balls too flat](#)392

It's easy to convert from bakers percent to weight measures.

First thing to do is to decide either how much flour you want to use or how much dough you want to make.

If you know how much flour you want to use :

Using your calculator, enter the flour weight then press "X" and enter the ingredient percent that you want to find the weight for, now press "%" and read the answer in the display window. Remember, your ingredient weights will be expressed in the SAME weight measures that the flour weight was expressed in (pounds, ounces, grams, kilograms, etc.).

If you know how much dough you want to make:

First find the sum of all of the bakers percents in your dough formula (it will usually be something between 165 and 175%), now divide this number by 100 (move decimal place two places to the left).

Using your calculator, enter the total dough weight that you want to make then press the division sign and enter the sum divided by 100 and press "=" and read the flour weight needed to make your new dough weight in the display window. Once you have the flour weight follow the above (first) procedure for finding the individual ingredient weights.

[Re: VWG percentage and hydration](#) **393**

The amount of diastatic malt FLOUR added to wheat flour is variable depending upon the amylose activity of the flour being malted. Flour in the U.S. is typically malted to a Falling Number of 200 to 250. As a general rule you can get close to this by adding 0.25% of a 20-L diastatic malt powder to an unmalted flour.

[Re: Confusing terminology in using the term "malt"](#) **394**

Pan Pizza Dough formulation:

Flour: 96%

VWG: 4%

Salt: 2%

Sugar: 2%

Shortening: 4%

IDY: 0.4% or ADY: 0.5% or CY: 1%

Water: 65%/variable (65F)

Mix dough just until it takes on a smooth appearance.

Target finished temperature: 75 to 80F.

Take to bench and scale (8.75-ounces/variable) and ball.

Lightly oil dough balls and CF for 24-hours.

Remove from cooler and allow to temper AT (NOT TO) room temperature for 2-hours.

Use a rolling pin or pastry pin to GENTLY open the dough to fit the pan.

Place the opened dough into a greased or oiled dark colored deep-dish pan.

Allow to proof for approximately 45-minutes (exact time will need to be determined by experimentation)

Dress as desired and bake at 450F.

Thin Crust Pizza Dough:

Flour: 95%

VWG: 5%

IDY: 0.4% or ADY: 0.5% or CY: 1%

Salt: 2%

Sugar: 2% (optional)

Oil: 2%

Water: 65%/variable (65F)

Mix until dough JUST comes smooth.

Target finished dough temp: 75 to 80F.

Take directly to the bench and scale at 2-ounces (for a 9" skin) and form into balls.

Lightly oil the dough balls and CF for 48-hours.

After CF remove from cooler and allow to temper AT (NOT TO) room temperature until the internal dough ball temperature reaches 50F.

Open into skins by your preferred method.

Dress and bake.

NOTE: A good way to CF the dough balls is to place each one into an individual plastic bag, twist the open end to form a pony tail and tuck the tail under the dough ball as you place it in the cooler.

Garlic breadsticks can be made using either dough by opening the ball to about 12-mm in thickness, forming into a rectangle shape and cutting into strips about 20-mm wide. Transfer cut strips to a greased baking pan and allow to proof for 30-minutes, then bake at 450F. As soon as breadsticks come out of the oven brush generously with a commercial garlic butter or make your own by combining butter with commercial garlic powder. then sprinkle with grated parmesan cheese and serve.

I'm not exactly what you mean by "stuffed garlic bread" please describe.

Subway Bread/Hoagie Buns:

Flour: 95%

VWG: 5%

Salt: 2%

IDY: 1% or ADY: 1.5% or CY: 3%

Shortening: 6%

Sugar: 4%

Water: 58%/variable (65F)

Mix the dough to a smooth consistency plus an additional 5-minutes (this will be variable depending upon the characteristics of your local flour).

Target finished temp: 80 to 85F.

Take dough directly to the bench, scale into 7-ounce pieces, form into balls, cover with a sheet of plastic and allow to rest for 20-minutes.

Using your hands, roll each dough ball into a hot dog shape (lightly dampen your hands with water if necessary) about 7-inches long.

Place formed dough piece onto a baking paper lined or lightly greased sheet pan with dough pieces spaced 2 to 3-inches apart.

Cover to prevent drying and allow to final proof for 45 to 60-minutes. You will need to experiment to determine the time best suited to your specific conditions.

Using a VERY SHARP SERRATED knife or razor blade cut 3 to 4-diagonal cuts (about 2-mm deep) across the top of each dough piece.

Spray with water and bake at 425F.

Note: If the finished buns are too flat reduce the water, if you want more spread increase the water (absorption).

This type of buns is typically not fermented, Subway uses frozen dough which is not fermented either.

[Re: VWG percentage and hydration 395](#)

The total formula sum of bakers percent is 168.15 divided by 100 = 1.6815

You want to make two dough balls each weighing 29.5-ounces = 59-ounces + 2-ounces for bowl loss = 61-ounces of dough will be needed.

Divide 61 by 1.6815 = 35.68-ounces of flour needed X 28.4 = 1013.38-grams of flour.

Ain't math great?! :D

[Re: Practice Dough 396](#)

Why not just make a typical N.Y. dough formula such as:

Flour: 100% (Pillsbury Bread/Bread Machine Flour which is widely available at supermarkets at a very reasonable cost)

Salt: 1.75%

IDY: 0.4%

Sugar: 2% (optional)

Oil: 2%

Water: 62% (65F)

Target finished dough temp: 75 to 80F

Make it as you do your regular dough and cold ferment for a minimum of 24-hours (48-is better).

Scale into 19.5-ounce dough balls, oil each dough ball, drop into individual plastic bags (like bread bags), twist the open end into a pony tail and tuck it under the dough ball as you place it into the fridge to CF.

To use, just roll bag down around the dough ball and invert over a flour dusted surface or a bowl of flour.

Flour dough ball and open into a skin by your preferred method.

If you don't want to make pizza you can always make a calzone, or brush the skin with melted butter and then sprinkle generously with a cinnamon-sugar mixture and bake. After cooling drizzle with a sugar-water icing or cut into strips and dip in the powdered sugar-water icing (you might recognize these as "Dipin' Sticks"), or just dock it well and bake at 400F as a flat bread.

[Re: Practice Dough](#)**397**

amolapizza;

You are not alone in your confusion. All too often we find that to many in the in all but the wholesale baking industry malt is just malt, some don't even realize that there is a difference (diastatic v/s nondiastatic) and well as a difference in Lintner Value. We see this happening here from time to time too. When you toss in dry v/s liquid confusion reigns supreme. This is why it's always important to identify the exact type of malt product we're using or referencing in a dough formulation.

Remember my story about the New Hampshire bagel producer that mistakenly got the wrong (diastatic) malt product that literally shut down their production lines.

Malt is an ingredient that has different applications in different industries which is why there are so many variants and making it important to identify specifically which product is being used or referenced. To the home baker it may not be a "big deal" if the wrong product is used since we are dealing with small amounts of dough but to a large scale producer, beginning with a pizzeria and going up from there it becomes a "very big deal" if the wrong malt product is used.

[Re: Confusing terminology in using the term "malt"](#)**398**

The old stand-by is to put the water in first, then the flour and dry ingredients and mix just until you don't see any dry flout in the bowl, add the oil and continue mixing (at a higher speed if possible) just until the dough takes on a smooth appearance. At that point the dough is sufficiently mixed, the dough might feel a little tacky but not sticky. Finished dough temperature should be in the 75 to 80F range when mixing is completed.

[Re: Dough tearing/blistering](#)**399**

I think your fermentation of the dough prior to scaling and balling is contributing to the problem. Try this, reduce the IDY by 50%, adjust the water temperature to

give you a finished dough temperature of 75 to 80F, then immediately after mixing the dough scale and ball it, place in UN-OILED dough box, lightly oil the top and sides of each dough ball (use canola oil), allow box to remain UNCOVERED for 2.5-hours, then cover/lid the box and allow to CF for 24-hours. Remove dough box from cooler (keep it covered) and allow the dough balls to temper AT (not to) room temperature until the internal dough ball temperature reaches 55F. Then remove dough ball from box and begin opening the balls into skins by your preferred method. The dough balls may deflate a little but not completely and they should open into skins pretty easily, there should be an improvement in oven spring which will promote crispiness in the finished crust.

[Re: Trying to get a good crisp... Thoughts? 400](#)

Oil is a tenderizer so adding 2% might help.

[Re: Dough is a little chewy and tough 401](#)

Please tell us something about your fridge, maybe a picture?

[Re: Dough tearing/blistering 402](#)

For me personally, I'd have gone with 0.05% IDY for what you were doing. It sounds like you are mixing the dough by hand so all you really need to do is to mix it sufficiently to have a cohesive dough and let biochemical gluten development take care of the rest of it for you. One other thing: When mixing the dough by hand it is highly recommended that the IDY be hydrated in a small portion of the dough water (tempered to 95 to 100F), just put the IDY into a small container of water and stir to hydrate the yeast making a uniform yeast suspension, you can then add the IDY suspension directly into the remainder of the dough water in the mixing bowl.

[Re: Failed Neapolitan dough 403](#)

Try removing the dough from the plate and re-ball it, then place it in the fridge to relax for several hours, it should be relaxed sufficiently for use by dinner time. Let us know how this works out for you.

Tell us about your oven too.

[Re: Failed Neapolitan dough 404](#)

This is what happens when one tries to cross reference terms from two different disciplines (brewing and baking) as many times the same word or expression has significantly different meanings. For example, the words "Do you have worms?" has an entirely different connotation to a fisherman than it might have to a doctor. :-D In the baking industry the word "malt" has a much more limited meaning and to some extent application, than it has in the brewing industry. In the baking industry barley is the primary source of malt and this is required, by law, to be stated on a bag of "malted wheat flour". In the baking industry malt is used either as nondiastatic (powder or liquid) as a source of sugar (maltose) for flavor and/or crust color development or as diastatic for the amylolytic conversion of a portion of the starch (primarily damaged starch) to sugar (maltose) as a yeast nutrient. Additionally, some research has shown that that a reduction of starch can contribute to a softer crumb structure in the finished product resulting in a potential improvement in perceived freshness of some bakery products.

[Re: Confusing terminology in using the term "malt" 405](#)

Wow! That's a lot of ADY considering that most people probably use not more than 0.5 to 0.75% at the very most. 1 to 1.5% ADY would be more in line with a no-

time/emergency dough that would be ready to go in about 2-hours after mixing. But in the end, if it gives you the flavor profile that YOU want, I cannot argue with you.

[Re: The effect of yeast percentages on taste](#)**406**

It's hard to beat fermentation and all of its nifty by-products for flavor. Malt, either to hydrolyze a portion of the starch to support long fermentation times or to provide a level of flavor by itself is a big part of the total flavor picture too. Note: This is based on the assumption that one likes the "fermentation" flavor, I know that not everyone does.

[Re: Either my dough is bland or my tastebuds are dead. Can I get some criticism?](#)
407

Unless you have a way to actually measure the pH and TTA (titratable acidity) of the sourdough starter you have no idea of what it actually is, that's one of the issues with sourdough starters, you never know for sure exactly what you have so it is not uncommon to have to experiment to determine the amount needed to achieve the desired results.

[Re: First Attempt Making Pizza with a Natural Sourdough Starter: No Elasticity!](#)**408**

I've literally hand cut thousands of dough balls and I still continue to weigh each one. In our pizza class we used to show our students how to speed up the hand cutting process by forming the dough into a rope and cutting the dough to length, use a scale to establish the length needed for the weight that you want, then begin cutting to length (length = weight). The best that I was EVER ABLE TO MANAGE was 7-consecutive pieces all within 1/4-ounce (that's 7-grams) of each other. Use a scale, it's a lot more accurate and consistent!

[Re: Dough Ball Weight](#)**409**

In all probability it was the problem. I'm guessing that it was either too strong for your flour or you used too much. I'd suggest making it again but use only half as much of the SD starter, if the dough performs better you'll know you're on the right track to solving the problem.

Being able to see your dough formula and procedure would also be very helpful too.

[Re: First Attempt Making Pizza with a Natural Sourdough Starter: No Elasticity!](#)**410**

That, my friend, would be a very safe assumption :-D. My ability to weld stainless steel, and access to the necessary equipment, along with my understanding of fermentation and access to malt (it was a certified bakery ingredient) made me a very popular person during my time over there. Almost got caught on two different occasions, would not have been a pleasant outcome. I used to say that the best kept secret was what we were making in those brew tanks (we used to call them liquid ferments).

[Re: Either my dough is bland or my tastebuds are dead. Can I get some criticism?](#)
411

I was working in the Aramco Bakery training the entire bakery staff from production to maintenance and sanitation. I was living at Steinekie Hall (spelling?) Except for the meals that I had at the bakery I used to eat at the Dining Hall (my good friend Hind Leithead) was in charge of Dining Services for Aramco, her

husband was Head of Airport Operations. I was the second to the last contractor to leave the country when they nationalized in 1980. Later, I served again as a consultant when the Saudi's built the frozen dough/pizza plant in Riyadh. I was at the Latif Bakery a number of times but I never paid much attention to their breads for the reasons mentioned above. I've still got pictures of me riding motorcycles on the desert and skiing on the sand dunes and a whole bunch of stories!!!

[Re: Either my dough is bland or my tastebuds are dead. Can I get some criticism?](#)

412

They're like rocks at a stone quarry, not terribly difficult to find.
Lots of previous discussion on peels too.

[Re: Long Handled Wooden Launching Peel](#)**413**

Mr. Peel or American Metal Craft are some options.

[Re: Long Handled Wooden Launching Peel](#)**414**

My preference is to tear the cheese as opposed to slicing it, this gives a thin edge to the cheese allowing for more of the transition that you mention.

[Re: How to get cheese to blend into sauce?](#)**415**

Hey! I was in Dhahran for 3-years, went to Khobar many times, just a hop, skip and a jump away.

Small world!

[Re: Either my dough is bland or my tastebuds are dead. Can I get some criticism?](#)

416

If you are trying to get that "pizzeria" flavor (not sure what that really is) you might try some of the following;

- 1) Reduce the honey to 2% of the total flour weight (325-grams).
- 2) Adjust IDY to 0.374%
- 3) Scale and ball the dough immediately after mixing.
- 4) Targeted finished dough temperature is 75 to 80F.
- 5) Lightly oil the dough balls and place into individual plastic bread type bags (NOT ZipLock Bags), twist the open end to form a pony tail and tuck under the dough ball as you place it into the fridge.
- 6) Cold ferment for 48-hours (this is how many pizzerias manage their dough).
- 7) Remove dough from fridge and allow to warm AT (NOT TO) room temperature until the internal dough ball temperature reaches 50 to 55F, then roll the bag down around the dough ball and invert over a flour dusted part of your work surface.
- 8) Flour both sides of the dough ball and open into a skin for immediate use.

Let us know if this moves you closer.

Also keep in mind that loss of smell is a possible indication of C-19 (smell is a BIG part of the flavor equation) :-D. Unless you have a control/target crust to evaluate against it is indeed possible to lose all ability to distinguish changes in taste or aroma/flavor.

[Re: Either my dough is bland or my tastebuds are dead. Can I get some criticism?](#)

417

65% absorption seems a bit on the low side for a dough made with 25% whole-wheat flour. What did the crumb structure look like? Was the dough slightly sticky or tacky when it was opened into a skin? If it wasn't the absorption was too low.

[Re: First cook in my Ooni Koda 16](#)**418**

Finished dough temperature?

Type of dry yeast?

Dough ball weight?

Pizza size?

[Re: Does thin crust mean crispier crust ?419](#)

Because the potassium iodate was found to interfere with some medical tests. The AMA asked the baking industry if it was possible to eliminate the use of iodate for this reason and the baking industry did as requested. Wanna know what replaced potassium iodate?

Answer: ADA/Azodicarbonamide. I was the one who did all of that work.

[Re: Bromated flour 420](#)

No, a thinner dough skin or crust does not always relate to a crispier finished crust.

Rather than going through a whole litany of things that can be done to provide for a crispier finished crust it would help if you could share with us your dough formula, dough management procedure and also tell us about your oven and how you are baking your pizzas.

[Re: Does thin crust mean crispier crust ?421](#)

They are due to either excessive drying of the dough ball (depending upon how the dough balls are stored it can be limited to a small area or a large area of the dough ball) or it might be dusting flour adhering to the dough ball (pretty common).

[Re: Crust dry spots422](#)

Actually, California doesn't ban it they just require that any product which contains it be labeled with the warning that this product contains potassium bromate, a known carcinogen and may cause cancer in some individuals (or something to that effect), yum, yum, I think I'll have another helping! Because of this and the fact that none of the chain stores or food manufacturers want the publicity associated with the use of bromate no one uses it in California and distributors don't carry it for that reason. Now, in Canada it's a different story as its use is officially/legally banned there.

[Re: Bromated flour 423](#)

HansB;

I'm putting my money on a meteor over bromate! :-D

Elchimi;

Since there is a readily available effective substitute for it it's really not all that commonly used anymore. It is used in some flours (at a very low level) due to demand for it in some markets. So, why don't the flour millers add the new bromate replacers to the flour? The answer is because none of them that I'm aware of are designed for stand alone addition to flour so for that specific application there is still not a suitable direct replacement.

[Re: Bromated flour 424](#)

It does serve a functional purpose in flour where long fermentation times are the order of the day. Do I think bromated flour is necessary? No, not in view of the fact that we have some excellent performing enzymatic oxidants that serve as a replacement for it. Do I go out of my way to avoid it? No. Is it really necessary in pizza production? When bromate came under scrutiny many years ago we looked at

just how important bromate was in pizza production. We found that as long as one had access to high protein flours capable of forming strong gluten with good fermentation tolerance it was not needed at all so in my humble opinion the use and necessity of bromate in pizza dough is a moot issue, in white pan bread and many variety breads of commercial manufacture it is a totally different story but again we now have some excellent performing bromate substitutes (as previously mentioned) so even in bread production it's a moot issue. It's certainly not like back in the 50's and 60's where bromate was being used at the outrageous levels of up to 75-ppm. One of my technicians once described the flavor of bread when made with bromate levels this high as "tasting like a swimming pool" and he was correct in his assessment. If you are old enough to have ever had continuous mixed bread aka batter whipped bread back as late as the 60's you have been exposed to these high levels of bromate.

[Re: Bromated flour 425](#)

Actually bromate is converted to bromide (a non-carcinogen) during the baking process and it wasn't until the 1970's that the Japanese developed a method for detecting bromate in PPB (parts per billion), it was then discovered, that in some cases bromate was a residual in some breads but it was only measured in PPB where as previously it could only be measured in PPM (parts per million) so it was then considered unsafe. When you look at the big picture of things that are carcinogens it is safer to eat bread made with bromated flour (not to exceed 15-PPM potassium bromate) than it is to breathe the air in most major cities. And then you have the issue of nitrates, and trans fats and don't forget acrylamides, the list just goes on and on. My personal advice is "Don't be stupid and drink from the bromate bottle, use moderation and enjoy life!"

[Re: Bromated flour 426](#)

Non-diastatic malt is a non-active (no enzyme activity) form of malt. It is used for both its unique flavor and as a source of sugar for crust color development. Unlike diastatic malt, you can go quite high with non-diastatic levels without creating significant dough handling problems (stickiness). Most bagel manufacturers use non-diastatic malt as they can use it for both flavor and color without developing the stickiness associated with diastatic malt. A number of years ago I had to make an emergency trip to up-state New Hampshire to visit a wholesale bagel manufacturing facility that was having a problem with the dough sticking to their bagel forming belts and nearly shutting down production. First thing I asked was "Are you using diastatic malt?" The answer was, "No, we use non-diastatic malt syrup". They confirmed that the malt syrup was indeed non-diastatic. When I got to the plant late that day I went directly to the ingredient scaling room and sure enough, the label on the 55-gallon drum said "DIASTATIC MALT SYRUP"!. So why did they answer "no" to my question? It seems that they checked their formula sheet, not what they were actually using....Oops! Yes, the wrong product was shipped to them by their supplier. I called the supplier and got the non-diastatic malt delivery started while we cleaned up the mess out on the production floor, a short time later we had the NON-DIASTATIC malt syrup and production resumed with no further issues. Lessons learned that day:

- 1) Always check ingredient name and product code number against your order manifest at the time of delivery.
- 2) When someone asks a question about an ingredient being used don't just look at the formula sheet, look to see what is actually being used.
- 3) Bagels are made from a pretty simple and basic formulation, the malt syrup was the only ingredient where a simple mix-up could result in disaster, they should have

been aware of that and gone directly to the #1 suspect to begin their own investigation. A little education goes a long ways.

4) The lesson that I learned, NEVER ASSUME ANYTHING, that's been well known for a very long time but sometimes we need a reminder.

[Re: Diastatic malt vs. non-diastatic](#) **427**

Maybe your flour is already malted either through the addition of diastatic malt or enzymes (alpha amylase)? The bag will tell the story if the flour is malted/treated with enzymes or not. Additionally, flours that are high in starch damage do not fare well at all in the presence of any amount of diastatic malt or alpha amylase.

[Re: Diastatic malt vs. non-diastatic](#) **428**

Let me hear an "AMEN" to that! ^^^

[Re: Diastatic malt vs. non-diastatic](#) **429**

Many of us here have the KD-8000 and I've not heard any complaints about it yet, at least none that I can recall. One of the best things about the scale is that it operates on regular flashlight batteries, I've had mine for years now and use it all the time and it's still operating on the original batteries supplied with the scale!

[Re: Scale](#) **430**

Like many things, a little diastatic malt can be a good thing if your flour is not already malted but too much of a good thing can really mess things up. A recommended use level for 20L diastatic malt is 0.25% based on the total flour weight....use more only if you dare. If the diastatic malt that you are using has a higher L (Lintner) value like maybe 60L you would use only 1/3 as much. No, flour manufacturers don't post anything about the flour absorption properties. The actual dough absorption used in making pizza doughs will vary with the following:

- 1) Type of pizza being made.
- 2) Dough making process.
- 3) Finished dough temperature.
- 4) Type of dough management employed and fermentation time/temperature.
- 5) Individual's proficiency/skill at opening the dough into a skin.
- 6) The type of oven to be used.

It is impossible for the flour manufacturer to know all of these parameters so any recommendation for dough absorption would be a total guess. If you want a S.W.A.G. here's mine for a starting point only:

Thin crispy & cracker type doughs: 50%

American style pizza doughs: 60%

Wood fired oven doughs: 65%

Neapolitan style doughs: 70+%

Like I said, this is just a S.W.A.G. as the final absorption will depend upon any number of factors including the absorption properties of the flour being used.

[Re: Diastatic malt vs. non-diastatic](#) **431**

Since your experimental program calls for assessing the impact of the various processing steps I would suggest that you begin with a a dough formula that you have confidence in for producing a decent pizza, it sounds like you might already have that.

Then begin by making your pizza a number of times to assess its "standard deviation" if you will. You will need to do this several times to reduce the "human"

factor in the variables. In essence, you are now producing a CONSISTENT pizza, regardless of quality, it MUST be consistent. If you don't do this you will never know if a change in quality characteristic was due to your normal variability or if it was due to the experimental variable.

With this done you are now ready to actually begin your experimenting. Select the variable that you want to test, let's say baking temperature. Prepare the dough by your standardized formula and procedure with the only experimental variable being the baking temperature (note: you will also need to adjust the baking time with the temperature as the two go hand-in-hand, so you will need to adjust the time to give a bake as close as possible to the control (your standard product). Make experimental adjustments to baking time and temperature to cover the ENTIRE spectrum for baking the pizza. Compare your experimental results to the control pizza that should be made on every test day. If you cannot make a control pizza on each test day document your control pizza with pictures showing diameter, height, top and bottom color, and crumb structure. Also be sure to document the mastication properties. You would be amazed at how much your perception of the quality characteristics will change over time if this is not done, at least documenting it for the control will provide some kind of a fixed reference point for comparison purposes.

Once you have done your testing on each of the variable it will be time for Stage II, this is where you begin looking at "cross variables" such as higher dough absorption with baking time and temperature as the experimental variables. This is going to be a long but rewarding study for you.

I've spent over 50-years doing it and I'm still learning new things all the time.

[Re: Seeking suggestions on how to approach troubleshooting disappointing results](#)**432**

I caught another tid-bit in what you said about the dough being pretty wet when you went to open it into a skin. I'm guessing that you are covering the dough boxes right away as opposed to allowing them to remain open until the internal dough ball temperature drops to 50 to 55F, then you can cover the boxes and kiss them good night. Does this sound familiar?

All of that condensation collecting on the dough ball tells me that the dough did not cool very efficiently which added to the amount of fermentation that the dough actually received, that combined with the water can be enough to result in the dough collapsing.

I don't recommend using a metal scraper of any kind on a plastic dough box, use only a plastic scraper.

Please P.M. me.

[Re: Trying to get a good crisp... Thoughts?](#) **433**

We make our dessert pizza bases by opening a regular skin then brushing it with melted butter and sprinkling well with a cinnamon-sugar mixture, add a streusel topping and bake just as you would any other pizza, allow pizzas to cool about 5-minutes and add a drizzle of powdered sugar-water icing. We add fruit slices and chopped nuts when we want to add the "WOW" factor.

In any case, regardless of how you make it, it makes for a tasty combination.

[Re: Adding cinnamon to dough](#)**434**

When you're up to needing 20 pizzas in as many hours this is not really the most opportune time to be experimenting with something that you have not ever used. Save the time for experimenting for those single or 2 or 3 pizza days.

You made the right decision! ^^^

[Re: Which yeast? Making 20 pizzas 20 hours from now](#)**435**

A friend of mine has the TC oven as described in Craig's attachment and I was thoroughly impressed with it! ^^^

[Re: Minimum Temp](#)**436**

OK, so the dough collapsed when you "pulled" the dough out of the box. You are not lifting it out using a plastic scraper, right?

Then, after you got the dough out of the box, what did you do? Details, details :chef:

[Re: Trying to get a good crisp... Thoughts?](#)**437**

Staging a sauced pizza too far in advance of baking can/will promote the development of the good old "dreaded gum line". The time will vary with your sauce and if you have oiled the skin or not. If you put a spoon of sauce on a saucer and leave it undisturbed for a period of time you will see syneresis taking place (loss of moisture from the sauce) if you note the time it takes for this to appear this will tell you how long you can hold the sauced skins prior to baking. You can also help to prevent damage to the dough by VERY LIGHTLY oiling the skin before the sauce is applied. This will create a barrier to moisture migration into the dough as the moisture leaves the sauce.

Pre-saucing is generally not a good idea as it does nothing good to the finished pizza so my advice is to keep the time as short as possible.

[Re: How long in advance to putting it in the oven can you fully stage a pizza](#)**438**

If you are going to degas the dough by mixing it you will need to mix the dough a bit longer to allow it to be balled without tearing.

[Re: Balling dough](#)**439**

Let's start by reviewing your dough formula and EXACT dough management procedure (be sure to include all times and temperatures), in all probability I'm guessing that's where we'll find the problem at.

[Re: Trying to get a good crisp... Thoughts?](#)**440**

All bets are "off the table" anytime a commercially made frozen dough has been subjected to thaw and re-freezing as the dough at that point is no longer considered to be commercially frozen (commercially frozen = freezing at -30 to -38F in a mechanical blast freezer with 600 to 800 linear feet of airflow per minute over the product or cryogenically frozen using liquid carbon dioxide or liquid nitrogen at -45 to -55F in the product zone. This establishes a small ice crystal formation in the dough which is less deleterious to the yeast cells and gluten network but when thawed and re-frozen at a higher temperature a much larger and more angular ice crystal is formed which is very deleterious to yeast survival as well as continuity of the gluten network in the dough. In short, commercially frozen dough that has been abused will not perform as well as the same dough that has not been subjected to the abuse.

[Re: Differences in store bought dough for digestibility](#)**441**

When I speak of "HIGH" protein content flour I'm referring to a flour with a protein content in the 13 to 14+% range which would be pretty typical for use in making a New York style pizza. For most other styles a protein content of 12 to 12.8% works well (Pillsbury Bread/Bread Machine Flour) which is available at many supermarkets is a good choice. For deep-dish and thick crust pizzas I

normally lean towards a flour in the 11.0 to 11.8% protein range.

[Re: hi gluten flour for nystyle pizza](#)**442**

The neat thing about working in bakers percent as opposed to true percent is that you can change any ingredient without changing the percent of any of the others. As long as you know your dough formulation it's also very easy to formulate in bakers percent to give you any size dough you want to make. Just divide the sum of the bakers percent of your formula by 100 and then divide your desired dough weight by this number, this will give you the flour weight needed to make the new dough size, now you can calculate the amount of each ingredient for the new dough size. For example: The sum of bakers percent is 162% divided by 100 = 1.62. We want to make a dough weighing 500-grams. Divide 500 by 1.62 = 308.64-grams (flour needed to make a 500-gram dough from your dough formula). Now just calculate the ingredient amounts based on 308.64-grams total flour weight.

[Re: Is This accurate?](#)**443**

I think what you are seeing has nothing to do with digestibility but instead everything to do with density. Frozen dough performance can be all over the board, especially when comparing doughs from different manufacturers. For example, how the dough has been stored (temperature and temperature fluctuation) and where the dough is at with regard to its projected shelf life will play a significant role in how the dough ultimately performs for the end user. This does not even take into account differences in dough formulation and processing which will also have a significant impact. It sounds like one of the doughs that you got was either at the end or close to the end of its shelf life or it might have been abused in some manner during distribution or storage either by a distributor or at the point of sale (more common than what you might think). By design, frozen dough has little to no fermentation so in essence products made from it would be construed as being less digestible than products which are made from a fermented dough (fermentation is a form of digesting, just ask any ruminant) so in a sense you might say that eating a product made from a fermented dough is actually eating a product which has been partially digested already (actually better tasting than it sounds).

[Re: Differences in store bought dough for digestibility](#)**444**

Some stores use a VCM (vertical cutter mixer) to cut their cheese. Be sure to use the sharp metal cutting blade as opposed to the dull one used for mixing dough. You might post this question over at the PMQ Think Tank <www.pmq.com>.

[Re: Cheese Not Melting Well](#)**445**

If you want to do a "Neo style" 600F but if you want to go traditional Neo you'll be looking for an oven that should be able to reach north of 800F.

[Re: Minimum Temp](#)**446**

Assuming you are using refrigerated cheese as opposed to frozen?

Assuming you have pulled the fingers from the top of the oven for cleaning?

[Re: Cheese Not Melting Well](#)**447**

Depending upon the type of "00" that you are using that might be waaayy too much fermentation. Plus if you are not proficient at opening the dough the "00" flours are not the most forgiving to work with.

If you want to continue with the "00" flour try using the dough after overnight fermentation, then after 24-hours and lastly after 48-hours, see if you see an improvement at one of these times.

You don't mention anything about your oven so I assume you are able to achieve a sufficiently high baking temperature (750+F.) to achieve a decent crust color. It is also suggested that you hydrate the IDY by suspending it in a small portion of 95 to 100F water before adding it to the dough water (be sure to include the water that the IDY is suspended in with the total dough water amount/%)

[Re: Too stretchy dough? 448](#)

I think if it were me, I'd just make the necessary number of pizzas (completely cooked), and hold them in some type of insulated container (anything to help keep them as warm as possible, then using a screen, place then back into the oven for warming and crisping (this should only take a few minutes for each pizza). If the pizzas are thin enough you may not even need a screen, just place directly on the stone to reheat (even faster). This is what many of the slice places do with very good results.

[Re: Dilemma: Four pies-one stone 449](#)

The KA bread flour is perfect. ^ ^ ^

[Re: Thin crust dough recipe from Dino's Gourmet Pizza \(St. Paul, MN\) 450](#)

Here's my approach;

Make your dough specifically for hot press forming (Summerset or Do-Pro).

Ferment dough balls 18 to 24-hours prior to press forming.

After press forming, stack 5-high with a piece of parchment paper between each skin.

Place in cooler for 2-hours, then form into groups of 3-stacks each and plastic bag.

Store in cooler until ready to transfer to truck for use.

Store under refrigeration in truck.

To fill an order, remove a skin from the stack, place on a seasoned screen, dress to the order and place on the infeed side of the oven conveyor.

Remove baked pizza from the outfeed side of the conveyor, transfer pizza to a cutting station and place screen into dough box for cooling (they cool very fast) and reuse.

This is a very similar method to that used by some of the fast casual pizza places.

Additional things for consideration:

You will need to have a state operating license and in addition to that you will most likely need to have a local license if you operate in a different county, city or town.

If you cross state lines you will need to be licensed for that state also. If you haven't already noticed, everyone is going to have their hand out.

Contact your local codes department to make sure what you intend to do is going to be approved, and GET IT IN WRITING!

[Re: Oven questions 451](#)

Might it also say one (1) cup lemon? I'd start at 1/4-cup and see what happens, then work up in 1/4-cup increments from there to 1-cup.

As strange as the recipe is it wouldn't surprise me if they used ADY but I'd rise above that and use IDY instead and add it on top of the flour.

Keep us posted on your progress.

One other thing, regarding their flour blend, you can essentially duplicate it using the Pillsbury Bread Machine aka Bread Flour available from most supermarkets.

[Re: Thin crust dough recipe from Dino's Gourmet Pizza \(St. Paul, MN\) 452](#)

For the dough you have two options, refrigerated dough balls that you might be able to have made by a local bakery to your specification (we can help you with

that). You will need to have the bakery refrigerate the dough balls and get them to you ASAP and then you will hold them under refrigeration (cold fermentation / CF) for 1 to 3-days. The process for managing CF dough is discussed in many posts here. The other option is to buy a commercially made frozen pizza dough (most distributors will carry it), the frozen dough is available as dough balls, dough pucks, and also as pre-sheeted skins. The dough balls and pucks can be thawed (slacked out) in the fridge overnight for use on the following day, or they can be slacked out overnight, placed at room temperature until the INTERNAL dough temperature reaches 50 to 55F and then placed back into the cooler for 24-hours. The dough MUST then be used in its entirety on the day after that 24-hour period. Any dough not used for pizza can be converted to other products such as garlic knots or bread sticks as opposed to being tossed out.

As you are trying to keep things simple without added labor I would suggest looking into one of the smaller electric air impingement ovens made by companies such as Edge, XLT, Lincoln or Middleby-Marshall. Remember that you will also need to add a small prep-station for assembling the pizzas as well as a cutting station unless you plan on using your existing kitchen for these tasks. Keep in mind that whatever oven you choose, electric or not, your local code will most likely call for it to be installed under a hood so be sure to check before ordering.

[Re: Dough balls, par baked](#)**453**

I have to admit, that is one of the more bizarre "recipes" I have ever seen for pizza dough!

Written up in such a haphazard manner that we can't decipher it how do the employees manage to follow it accurately? The "pinch" of salt makes absolutely no sense at all (why even put it in?). The 1/2-cup of garlic powder is another one, garlic powder, like onion powder is a very effective reducing agent and anything over 0.15% in the dough will soften the dough. I'm betting that 1/2-cup exceeds this amount by a good margin. The only reason for using it at this level would be to enable using the dough very soon after mixing and the pictures of the skins seem to confirm this (very little to no real fermentation). The 1-Tsp. cinnamon isn't enough to contribute a flavor so why include it? The lemon juice is just a source of citric acid which helps to acidify the dough, this might possibly be done in light of the fact that the dough is a very short time dough or possibly a no-time dough.

Commercially we acidify doughs too but we use vinegar since acetic acid is a by-product of yeast fermentation. If I read the flour correctly there is 23.5-pounds of flour in the recipe with 3-quarts (6#) of water, 1-quart of milk (about 28.16-ounces of water), 8-eggs (12-ounces water) and 2-quarts of oil, for simplicity let's call it 10.75-pounds of liquid so 10.75 divided by 23.5 X 100 = 45.74% absorption equivalency. I'd say this relates well to the pictures of the dough and the finished pizzas. The question is what kind of yeast is used and how much lemon juice is being added.

By the way, 1-pound of cinnamon would contain sufficient cinnamic aldehyde to stop the yeast dead in its tracks.

[Re: Thin crust dough recipe from Dino's Gourmet Pizza \(St. Paul, MN\)](#)**454**

Hopefully she has sufficient sugar in the dough formula to give some crust color development at that low of a baking temperature. Also keep in mind that she is making a focaccia type of pizza which in many cases really doesn't have a lot of crust color development as it is what many might describe as a bready type of pizza.

[Re: oven temp puzzles me](#)**455**

pepe123;

Papa Murphoys has a sweet tasting crust. We used 5% sugar in the dough formula to replicate their level of sweetness. Remember though that you will need to bake your pizzas at a lower temperature (400 to 450F) to control crust color development during baking. Of course, if you want it sweeter you can always add more sugar but keep in mind that with 5% sugar you will need to increase the yeast level (0.5 to 0.65% IDY with 5%) and even more as you increase the sugar level.

[Re: sweet pizza dough](#)456

The pressing question is, where are you planning to make the dough? How about storing the dough? There are bread trucks and there are bread trucks, what size box does yours have? There won't be a lot of room after you add an approved sink, storage, prep, mixing, work space and oven, then add the sales area. For the oven, gas (propane) or electric. Remember gas storage or a generator. Would really like a little more information.

[Re: Oven questions](#) 457

Looks about par for the course, I just tear those bubbles open and go on with life.

[Re: Is this as expected?](#)458

If the health department will allow it, butcher block without a doubt, my second choice would be man made quarts....about as close to indestructible as you can get.

[Re: marble, quartz or a granite top as a bench for shaping/stretching pizzas?](#)459

To answer your second question, as a rule once the dough is ready to begin opening and the dough is being held at room temperature, you window of time to open the dough is about 2-hours before you begin to see strange things happening. It's hard to answer your last question as it depends upon room/fermentation temperature, yeast level, dough absorption and flour strength. I'll make a S.W.A.G. and say that you should be able to begin using a 24-hour dough after about 18-hours.

[Re: dough storage while cooking?](#)460

Chet;

Are you talking C or F. in temperature? "C" (Celsius) would make prefect sense but "F" (Fahrenheit) would be way to cold of an oven for baking pizzas. This is not to say that it cannot be done but I would seriously question it. Many of those old wood fired or coal fired stoves (I was raised with one) had a major problem, that was getting too hot. I can remember things being baked and at some point the oven door was cracked open to reduce the heat. I'm guessing that those pizzas might have been baked at a much higher temperature than what you might be thinking. Is there anything else that you can provide us on those pizzas? Size, thickness, what were they baked on? In general terms what type of pizza were they closest to?

Any additional information will help.

[Re: oven temp puzzles me](#)461

In one word.....no. several hours, not a problem, overnight.....probably not unless you reballed the dough.

[Re: Is this ready?](#)462

There is nothing fixed about the length of time the dough needs to rest at room temperature after CF before it is opened into a skin. Pizzerias will typically look for

an internal dough ball temperature of 50F before beginning to open them while many home pizza makers look for something closer to 60F. A lot of it will depend upon your abilities at opening the dough. Remember that the colder the dough is (within the 50 to 60F range) the easier it is to open if you are not proficient. If you typically make 3 pizzas at a time you might want to target the 50 to 55F temperature range for your opening temperature, then as you become more proficient (faster) you can increase the opening temperature to make the dough balls easier for you to open.

[Re: Neapolitan dough and warm up time](#)**463**

I've used the trays/dough boxes from WRH Industries <www.wrh.net> Paul Bartley V.P. Sales & Marketing <pbartley@wrh.net> for years without a single problem. I can highly recommend then.

[Re: Warped Dough Trays](#)**464**

Cooking down the tomatoes doesn't change the pH, think of it like this, if you have a cup of white vinegar and measure the pH it should be about 2.5 to 2.7, if you add a cup of water to it will the pH change? Answer: no, only the TTA titratable acidity (concentration of acidity will change). Citric acid is used by manufacturers to ensure food safety of their canned tomatoes mostly because it is effective and it is also the main acid present in the tomato so it will have little to no impact upon the flavor of the canned product. Tomatoes are all over the board when it comes to pH. The pH of the tomatoes is dependent upon the variety and also upon the ripeness. Commercially, only the first picking is used for canned tomato products but even with that there is some amount of variability of ripeness within that grouping so it is necessary to adjust the pH of the tomatoes at the time of processing. When growing tomatoes at home you can hand pick your tomatoes at peak ripeness, which is impossible to do on a commercial basis. With all of the new tomato varieties being developed for the home gardener it is always wise to know the pH of your tomatoes at the time of processing, remember most new varieties are of a low acid type (not conducive to home canning as is), failure to do so may prove to be fatal.

[Re: Growing Your Own Tomatoes](#)**465**

I'm not you, but if I were, I'd remove the dough from the container (very carefully) and place it onto an oiled plate, flattening the dough as I did so (to about 1-inch in thickness, then lightly oil the dough and cover it with a piece of plastic. Remove it from the fridge about 30-minutes before opening.

[Re: Is this ready?](#)**466**

It really doesn't increase gluten formation, it just strengthens the gluten which makes the dough more elastic. By putting the salt into the dough water the dough forms more quickly, giving us the smooth appearance faster with less mixing time so there is less heat build up due to bowl friction as well as less wear and tear on the mixer. Remember, the target for mixing a pizza dough is to achieve the smooth appearance as quickly as possible (long mixing times make it more difficult to consistently hit our target finished dough temperature), not to fully develop the gluten. Additionally, from the time a dough begins mixing until it begins to change in density is roughly 30-minutes, depending upon dough temperature and yeast level, so if a dough can be mixed in 10 to 12-minutes we will have 18 to 20-minutes to get the dough processed and in the cooler but if we mix the dough for 20-minutes, that time is reduced to just 10-minutes (the yeast activates during the mixing cycle) and you can only guess as to what that long of a mixing time will do

to the finished dough temperature.

Why do we mix a pizza dough?

1) Disperse ingredients uniformly throughout the dough mass.

2) Hydrate ingredients.

3) Develop just enough gluten to retain dough ball shape and reduce/eliminate stickiness.

4) Achieve desired/targeted finished dough temperature.

[Re: Very airy dough](#)467

I agree, adding the ADY suspension at 6-minutes before the end of the dough mixing procedure is a bit different (although this is very close to one of the manufacturer's recommended procedures for adding IDY) Note: ADY suspension and IDY are two very different animals). I don't think it would cause any real issues however, I really don't like to add liquids late in the dough mixing process (especially if those last minutes will be hand kneading) due to concerns of not getting the liquid (ADY suspension) in this case, thoroughly incorporated into the dough.

I've said it many times, flour is the #1 biggest variable when it comes to dough ingredients. It's the nature of the beast.

As a note of interest: This is the time of the year when flour mills are getting into using the new year crop so don't be surprised if you find that you need to make adjustments to the dough absorption. New crop year flour is like that "box of chocolates".

[Re: NY style dough prep in summer; what's different](#)468

Agreed! You're ready to begin making pizza! ^^^

[Re: Is this ready?](#)469

Consider every mistake to be a learning opportunity and you'll never stop getting smarter! :-D

[Re: Dang, forgot to take dough out of fridge - Suggestions?](#)470

Adding the salt later in the dough mixing process is commonly used in bread production as a means to develop the gluten more rapidly during the mixing process. On many cases it is added about 5-minutes before the end of the mixing process, but again, that's for bread production only. In pizza dough production we are not looking for nearly as much gluten development (we typically mix only enough to achieve a smooth appearing dough) so it is more common to add the salt right up front (usually with the water) but many also opt to add it on top of the flour too. Remember, we are not looking for the gluten development of a bread dough. Both salt and sugar can/will inhibit or slow yeast activity but this only happens if you leave the yeast in contact with the salt or sugar for any appreciable length of time. When putting the salt into the water it is common to then put the flour in the bowl and the yeast on top of the flour (machine mixing only). When mixing the dough by hand the yeast is commonly mixed into the water containing the salt (cy can be mixed directly into the water but ADY needs to be activated and IDY needs to be hydrated separately before adding it to the water), the flour is then immediately added and the mixing process started. It should also be noted that for hand mixing the oil is generally added to the water too as this ensures better dispersion but when machine mixing it is better to mix the dough about 2-minutes (until you don't see any dry flour in the bowl) and then add the oil, this delayed oil addition procedure prevents the oil from interfering with the gluten development.

[Re: Very airy dough](#)471

You also need to see what the top looks like to make an accurate determination.

[Re: Is this ready?472](#)

I've always said that I never had a pizza that I couldn't learn to like but I had to make an exception when I tried Wheat State Pizza here in Manhattan, Kansas a number of years ago :(

They didn't last very long either....gee, can't imagine why??????

[Re: What is the worst pizza you have eaten?473](#)

If you are mixing the dough by hand there may be some advantage to dissolving the salt in a portion of the dough water but if you are using a dough mixer there is no need to do it unless you are using a coarse salt. When I mix my doughs using a mixer I always put the water in the bowl first, then add the salt and sugar (if used) followed by the flour. No need to stir/whisk or mix the salt into the water. I then add the IDY on top of the flour and mix using the delayed oil addition mixing method.

[Re: dissolving salt in a % of recipe water?474](#)

Gluten is the material formed by the wheat flour proteins glutenin and gliadin, these proteins are generally present in greater quantity when there is more total protein in the flour. It is the formed gluten that is responsible for binding the dough together and giving it the unique elastic properties that we look for in a dough. During fermentation the yeast produces byproducts (acids, alcohol and carbon dioxide) which work to weaken the protein (think of marinating a tough piece of meat), plus the yeast also carries with it enzymes which work to convert some of the starch into sugar for the yeast to feed upon (these are amylase enzymes) another enzyme present is protease/proteolytic enzymes which hydrolyze proteins and weaken them to provide the desired extensibility properties needed so the dough can be easily opened into a skin without excessive dough memory characteristics aka "snap-back", so no, it is not the yeast itself doing the work on the proteins but instead it is their byproducts that do the work and the longer you allow the dough to ferment the more impact those byproducts will have upon the characteristics of the finished dough.

[Re: Why does more gluten mean a longer ferment?475](#)

In a pizzeria we can force the dough balls by flattening them to about 1/2-inch in thickness and placing them onto a warm (100 to 120F) surface and lightly oiling to prevent drying, by this method the dough is usually ready to open in less than 10-minutes. We actually developed a shelf liner which could be installed over a heated holding shelf just for this purpose.

[Re: Dang, forgot to take dough out of fridge - Suggestions?476](#)

To a great extent yes, but you may find that you will need to place a screen under the deep-dish pizza if the bottom gets too much bake.

[Re: NY style in electric deck oven477](#)

My concern is the word "around", an estimate would be "around" but a thermometer only gives a specific temperature. In any case I'm sure CDennis will set us straight.

[Re: NY style dough prep in summer; what's different478](#)

For the olive oil, go with 2% and you'll be fine.

[Re: New member Hydrator](#)**479**

Welcome! You came to the right place.

Let us know what kind of equipment you have (scale, mixer, something about your oven) and what kind of pizza you're interested in making.

What part of Alaska?

[Re: Pizza in Alaska](#)**480**

Nice try, but chick pea and lentils don't contain any gluten forming proteins. All you are adding is a protein supplement, you would get a similar result by adding a protein drink base to the flour. In short, it will not increase the strength of your flour, it will make it more nutritious (from a protein stand point), but not any stronger.

[Re: Protein flour as additive?](#)**481**

A yellow flag jumped out when you said "reducing the water temperature to room temperature". To me, this says that the water temperature might be too warm resulting in a hot dough condition which most certainly will contribute to the stickiness you've been experiencing. My question to you now is: What is the finished dough temperature? A common water temperature is 60 to 65F and a typical finished dough temperature is in the range of 75 to 80F. Let's see how your numbers compare to these for starters.

[Re: NY style dough prep in summer; what's different](#)**482**

It sounds like you were making a high absorption dough and trying to bake it on a screen as opposed to a stone or baking steel. Yep, that'll get you into trouble more times than not. :-D

Tell us what kind of pizza you're trying to make...a N.Y. style? How do you mix your dough, by hand or machine? This is one site where T.M.I. is seldom ever an issue, unless it gets too personal.

Share with us what you are trying to achieve and somebody here will be glad to chime right in and help you get to where you want to be with your pizza making endeavors.

[Re: Hello to anyone who actually reads these things](#)**483**

With a smaller size dough sometimes the dough can get kicked around in the bowl by the "J" hook and receive some gluten development in the process but when the dough is of any size it just clings to the bottom and sides of the bowl getting very little actual agitation in the process. Or at some point the dough will develop gluten after which it then clings for dear life onto the hook and won't come off so it gets almost not further development when this happens. The only options are to continually stop the mixer and pull or cut the dough off of the hook (not very effective) or to increase the mixer speed thus allowing centrifugal force to hopefully pull the dough off of the hook.

In any case though, you only need to mix the dough JUST until it begins to take on a smooth appearance, more mixing than that is not needed not is it usually desirable as it contributes to a more bread like crumb structure in the finished crust as opposed to the desirable open, porous crumb structure which contributes to the crispiness of the finished crust. The "window pane" test for assessing gluten development is used almost exclusively for bread and buns but seldom for pizza.

[Re: Scaling dough recipe](#)**484**

You don't say how much yeast is being provided by the poolish but you are correct,

if the poolish is still active and healthy you normally don't need to add any more yeast.

[Re: yeast amount for final mix using poolish](#)**485**

Generally speaking, the thickness of the pizza will be determined by the type of pizza you are making, not be the amount of toppings applied to it. An example of this would be the difference between an American thin crust (think Domino's) and a Pizza Hut pan style pizza where for all practical purposes the amount of toppings is the same for both pizzas but the amount of dough and the finished crust are significantly different.

[Re: Thickness of Pizza](#)**486**

I'm not sure I'd go that route with the double yeast. Instead, just go with 0.5% IDY and then proceed as you have outlined, I think you will have a much better end result.

[Re: Transporting dough over long distances](#)**487**

Yael brings up a good point with the mountains, while we know that altitude will affect how a pizza (dough in general) bakes, we know that we may need to make adjustments in our dough formulation to account for this, it can also affect how the dough looks and feels, so it would be good to know the altitude that the "rural town" was located at.

[Re: I'd like to know what is going on](#)**488**

Yep, just add it right up front, no need to delay its addition at the 6% level. I add the solid fats tight on top of the flour. HOWEVER, if you melt the butter (or any solid fat) it now acts like an oil, at least until it re-solidifies, so if it's melted it should be treated as an oil. If it's only softened you don't need to delay its addition either, which brings up a good point, if the butter is cold it may be too hard and not get thoroughly incorporated into the dough within most dough mixing time parameters, so it's best to use the butter at room temperature.

[Re: When to mix in butter?](#)**489**

In addition to Yael's questions, do you have a reverse spiral dough agitator or a "J" hook on your mixer?

Planetary mixers without a reverse spiral dough arm are notoriously sensitive to the amount of dough in the bowl.

[Re: Scaling dough recipe](#)**490**

A lot of what you mention as differences could possibly be due to differences in the VWG. There are different types of VWG and when you get it from different manufacturers there is a possibility it could perform differently. Is there any way you can make the same dough in the city but using the same brand of VWG as was used in the rural town?

Differences in the water, especially the hardness/mineral content might be a contributor but in this case I don't think it's the culprit.

Since you are using IDY, how do you add the IDY to the mixer?

How about the age of the IDY that you used in the city? How long have you had it? How has it been stored?

[Re: I'd like to know what is going on](#)**491**

After some trepidation I did cut my own hair, in fact, I've cut it several times now and I have to say that I'm more than pleased with it. I'm using a #4 attachment for

the sides and a #6 for the top. Then go to the #2 for the back of the neck and trimming close around the ears. It's so easy that I can't see ever going back into a barber shop again.

[Re: Haircuts in an Age of Lockdowns and Self-isolation](#)**492**

To achieve a stronger (darker) crust color just increase the amount of malt or sugar.

As for storage of the diastatic malt, like I said, condensation is the big issue. If the package is unopened there is no problem at all BUT you MUST be sure to allow the malt to THOROUGHLY warm to room temperature before opening or you will get condensation on the malt which over time, will lead to severe lumping. Because the stuff is so hygroscopic the condensation will quickly be absorbed into the malt powder, this will be repeated each time the package is opened for use. I have personally seen a near full bag turned into a single block of malt in just a few months, and this was with refrigerated storage (opened for use two to three times a week). The condensation issue is pretty well negated with room temperature storage but remember that each time the package is opened you are allowing more humid air to replace the desiccated air inside the package and the above process continues however at a much slower rate.

The key to effective storage of diastatic malt powder is to minimize the head space in the package, leave it in the original packaging and fold the package down tight to the contents after opening and after each use, secure well using a rubber band and hope for the best. It should go without saying that those living in a drier climate will experience fewer issues than those living in an area with high humidity. The same can be said for summer and winter, with fewer issues in the winter due to the drier air and more in the summer when the relative humidity is significantly higher.

[Re: kindly help please](#)**494**

I've not personally used one of these ovens but I've seen them at Pizza Expo and I don't know anyone who has one.

[Re: Doyon Pizza Oven?](#)**495**

It sounds like you are looking at the Doyon Jet Air Pizza Oven (PIZ3). You should be able to Google this to get more information on the oven.

[Re: Doyon Pizza Oven?](#)**496**

I bake my American style pizza right on the screen. Just make sure your screens are seasoned, if they are not seasoned the pizzas will stick to the screens and you will have a difficult time separating the two. As you continue to use your seasoned screen(s) they will continue to darken (a good thing) which will further improve the baking properties of the screen. Do NOT wash a seasoned screen, just wipe it down with a clean towel or paper towel after each use. Once you begin to get some color on your seasoned screens they do not need to be oiled for each use (I do suggest lightly oiling the screens before each use even after seasoning) for the first few bakes though.

[Re: What style of pizzas yield good results without a stone/steel?](#)**497**

Rolls;

Sweet dreams..... :-D

[**Re: Storing Brioche Hamburger Rolls498**](#)

Do you have a scale capable of weighing in grams?

Please tell us something about your oven.

What kind of pizza are you wanting to make?

[**Re: San Diego newbie, seeking the perfect pizza dough recipe499**](#)

Absolutely! No different from most of the premium breads, rolls and pastries sold at the local supermarket. The only reason why some pastries have to be refrigerated is because they have some kind of perishable filling inside them (like my favorite....the chocolate eclair) or a cheese Danish which may not need refrigeration if the cheese mixture is applied pre as opposed to post bake. Even the butter that you're putting onto the crust immediately after baking will not warrant refrigeration.

Just store at room temperature, and even if it's a little warmer it won't hurt at all.

[**Re: Storing Brioche Hamburger Rolls500**](#)

Sure! ^^^

[**Re: Final Dough Temp and freezing dough balls501**](#)

You're in a conundrum in that you want to use the same dough for freezing (0.5%, or more IDY recommended) and for cold fermentation (0.2 to 0.4% IDY recommended). So you have to compromise, low end for frozen dough and high end for CF which is, in my opinion, 0.5% IDY.

[**Re: Final Dough Temp and freezing dough balls502**](#)

Rolls;

To retain maximum freshness in the buns, if you are going to use the walk-in cooler, first turn it off and allow it to warm up to room temperature or better yet, 85 to 90F. Refrigerated temperatures are the temperature at which bakery foods stale at their fastest rate. The slowest staling is experienced at 85 to 90F., but not for more than 3 to 4-days as after that mold is going to be the issue not staling.

My advice:

Brush with melted butter or Ghee.

Allow to cool to 95 to 100F.

Place into plastic bags and close using a twist tie.

Store in a warm area until used on the following day.

[**Re: Storing Brioche Hamburger Rolls503**](#)

First off, your salt level is rather low at only 0.76%, for flavor, dough strength and controlling the rate of fermentation I'd suggest increasing it to 1.75% or as high as 2.5%.

As for the finished dough temperature, in most cases I would say that 70 to 75F might be a bit to cold for a cold fermented dough going into a walk in cooler, but for a reach-in commercial cooler it is the recommended temperature range, and since a home fridge is nowhere as efficient as a commercial reach-in cooler I think you will be fine using the same dough for your CF process.

[**Re: Final Dough Temp and freezing dough balls504**](#)

Here is a process that might work for you, I can't say for sure as I don't know anything about your shop conditions or much else for that matter.

This is an adaption of an emergency pan dough method, please keep in mind that

the dough as presented is good for a single day but you can always try it on the second day to see if it will perform to your expectations, if not, any remaining unused dough at the end of the day can be made into bread sticks or garlic knots and par-baked for later use or it can also be incorporated into new dough at up to 15% of the new dough weight.

Flour (12 to 12.8% protein content) 100%

Salt: 2%

Sugar: 2%

Fat: 4%

IDY: 0.5%

Water: (65F) 62% This may need to be adjusted as all flours are a bit different.

Put water in mixing bowl, add salt and sugar, add flour and IDY.

Mix about 2-minutes at low speed or just until you don't see any dry flour, then add the oil/fat.

Mix one more minute at low speed, then mix about 8-minutes at medium speed or JUST until the dough has a smooth appearance.

The dough is now done mixing. Check the finished temperature, you want it to be in the 75 to 80F range.

Take the dough directly to the bench for processing. It must be completely processed within 20-minutes.

Scale and ball the dough. Place into dough boxes and lightly oil the top of each dough ball.

Place in cooler in a cross-stacked manner until the INTERNAL dough ball temperature reaches 55F. Then down-stack.

Allow the dough to cold ferment for 18 to 24-hours.

On the following day, remove dough from cooler and immediately place into dark colored, greased deep-dish pans. Flatten the dough into the pan as well as possible OR you can pass flatten the dough balls on the bench and place into the pan.

Cover the pans with a large sheet of plastic or some other manner and allow to proof for 60-minutes in a warm location.

Press the dough out again (in the pan) and allow to continue proofing for 20 to 30-minutes, if the dough hasn't pulled away from the pan don't touch it, if it has pulled away gently press the dough again to fit the pan.

Here is where you will need to experiment:

Place two pans of dough in the cooler, then in 30-minutes place two more pans in the cooler, then in 15-minutes 2 more pans and again after another 15-minutes (in total there will be a difference of 2.5-hours between the first two pans and the last two pans going into the cooler. After the last two pans are in the cooler remove the first two pans, dress and bake (about 7.5-minutes at 475F) in an air impingement oven. At the same intervals that they went into the cooler remove the pans of dough (in the same order) and dress and bake. Assess each pizza after baking to determine which proofing time provides you with the best finished pizza. The process may need to be tweaked a bit for your specific shop conditions but this should get you on the right track and close to where you want to be.

This process will allow you to work your deep-dish pizza straight out of your cooler inventory so as long as you have an inventory in the cooler you will have deep-dish pizzas to bake. Unless you have a LOT of deep-dish pans you will need to repeat this process at some point during the day to rebuild your inventory in the cooler.

[Re: kindly help please](#)**505**

Peter;

I most cases cold water won't cut it due to the longer mixing time needed, but if

you can live with 10 to 15-days shelf life you can put the greater gluten development on the back shelf and maybe get away using straight ice water, or something close to it. In many cases we have to use ice as part of the water, if you do this be sure to weigh the ice and subtract an equal WEIGHT of water from the formula.

Chilling the flour can help if you are not mixing to a greater level of gluten development, otherwise it is counter productive as it takes longer to develop the gluten in cold or frozen flour which lengthens the mixing time which creates more heat due to bowl friction.

In commercial operations we use mixers with direct expansion jacketed mixing bowls the get so cold that they will freeze the dough to the bowl if the mixer stops with the bowl cooling turned on. They also super cool the flour by injecting carbon dioxide into it, however they also add glutathione or L-cysteine to the dough to reduce the dough mixing time. It needs to be noted that all of this produces a dough that is VERY TOUGH and hard, it is so tough that highly specialized horizontal mixers with dual drive are a standard feature. I might also add that both L-cysteine and glutathione are counter productive to achieving a long (16 to 20-weeks) shelf life so commercial frozen dough will also contain some type of a coated (think time release) oxidant such as ascorbic acid, azodicarbonamide, or possibly one of the newer enzymatic oxidants, which kicks in after mixing to counter the effects of the reducing agent used (L-cysteine or glutathione).

[Re: Final Dough Temp and freezing dough balls](#) **506**

Tscarborough:

Your question leads me to believe that you may have never been on a "pizza" date!

:o :-D :-D :-D :-D

[Re: What are the Surprising benefits of consuming pizza to promote Good Health?](#) **507**

Absolutely! It's the final dough temperature that is causing the dough to ferment even though its in the freezer. In a home freezer it can easily take a day or more for a 500-gram dough ball to thoroughly freeze (it ain't frozen until the core is frozen). In one test we did many years ago the core of a 500-gram dough ball still wasn't frozen after 3-days in a home freezer! The good news is that the dough, even though it has been fermented will perform pretty well out to something in the 10 to 15-day range, after that it's a crap shoot as to how well the dough will perform, if at all. For home use, who cares if the dough doesn't perform up to snuff? You can always make a few adjustments and skate by, but in a commercial application that bucket doesn't hold water as the dough has to ALWAYS perform up to the customer's expectations, even in view of abuse bestowed upon the dough at the hands of the distributor, merchandiser, and the end user!

You can hedge your bets and get optimum performance from your dough by doing the following:

Target finished dough temperature at 65 to 70F.

Mix the dough to near full gluten development.

Scale and ball IMMEDIATELY after mixing.

Flatten the dough balls to 1 to 1.5-inches thick.

Lightly oil the dough "pucks".

Place on aluminum sheet pan (better heat transfer) for freezing.

Dough should go into the freezer ASAP after mixing and forming.

Plastic bag the dough pucks only AFTER the core temperature reaches the +15 to +10F range.

To use the frozen dough:

Remove from freezer and allow to temper AT (NOT TO) room temperature until the core temperature reaches 55 to 60F.

Place into the fridge to begin the cold fermentation process.

Note: Frozen dough formulas will typically contain 1.5 to 2 times the normal yeast level for the product being produced, this is to adjust for the yeast cells destroyed and/or damaged during the freezing process. In a home use setting failure to do this will usually result in a slower than normal fermentation rate that may not even be noticed as we automatically adjust for it by just allowing the dough to ferment or proof longer, commercially though this is not a viable solution, hence the higher yeast levels.

[Re: Final Dough Temp and freezing dough balls](#) **508**

Please let us know how it turns out and if you can, send some pics.

I don't know what you plan to store the dough balls in but to get started you might use the individual plastic bag method. We have discussed this method here previously so I won't go into the details: oil dough ball, place in plastic bread type bag, twist to close, tuck twisted end under dough ball as you place in in the fridge, bring out and allow to set AT room temperature for about 2-hours before opening into skins for immediate use. NOTE: These is no cross-stacking or leaving anything open with this method....very convenient. :)

[Re: Help fine tune a cold fermented NY/American dough recipe](#) **509**

I will address some of your questions to help you get started with food for thought.
Flour: I would recommend using the KABF as it has a higher protein content and is better suited to longer fermentation times.

Absorption: I suggest beginning with 62% for long fermentation times and then work up from there.

Fat: You can use olive oil if you wish, I suggest using a pomace grade olive oil as it will provide a better flavor when used IN the dough.

Yeast: Use IDY at 0.25%. Add it directly to the flour. IDY is very stable and is easy to use.

Salt: If you like things salty go for 3%, but I recommend 2 to 2.5%.

Sugar: 2 to 3% should work fine for you.

Process: An autolyse really isn't needed with dough absorption in this range. If you "have" to use it this is a good time to catch up on some reading. No yeast in an autolyse if you do put it in it is a biga and totally different.

Adding Ingredients: Add the water, then add salt and sugar (no need to stir or whisk), add flour with IDY last on top of the flour. Mix at low speed just until you don't see any dry flour, then add the oil and mix one more minute at low speed, go to medium speed and mix JUST until the dough takes on a smooth appearance (typically about 8-minutes). Targeted finished dough temperature is 75F.

Take dough DIRECTLY from the mixer to the bench, scale and ball, lightly oil each dough ball, place in fridge UNCOVERED until the INTERNAL dough ball temperature reaches 50F then cover for the duration of CF. Cold ferment for 72-hours (experiment).

To use the dough, remove from fridge, allow dough balls to warm AT (NOT TO) room temperature until the internal dough ball temperature reaches 60F.

Depending upon your skills, if you find it difficult to open the dough at this temperature open the dough at 50F, so I'd suggest trying one at 50F and deciding if you want to allow it to warm more or not...your call.

Bake on a dark colored/seasoned screen or pan or if you have one, a stone or steel. Bake at 500F if possible.

[Re: Help fine tune a cold fermented NY/American dough recipe](#) **510**

Store it like you would brown sugar, remember it's extremely hygroscopic. Never refrigerate it, it won't hurt it but it will only promote condensation...not a good thing.

[Re: Diastatic Malt - How to adjust for different Lintner strengths?](#) **511**

Following the old KISS principal;

Mix

Finsihed dough temp @ 70 to 75F.

Take immediately to bench for scaling and balling.

Oil the dough balls and bag individually (we have discussed this method a number of time previously).

Refrigerate overnight.

Box in cardboard cases and transport to event.

Store under refrigeration

Use the dough directly from the refrigerated cases.

Open into skins, dock well, dress to the order and bake.

[Re: Dough management for summer festival](#) **512**

Did the dough formula that you "followed" say it was suitable for freezing?

My emergency dough formula is intended for immediate use only! It has not been formulated for freezing. Doughs that are formulated for freezing will have high sugar,salt and yeast levels, they will be mixed to near full gluten development and they will not be fermented prior to the freezing process, additionally the dough balls are almost always flattened to about 1.5-inches thick to facilitate rapid freezing if the dough. Dough that is not blast frozen (-35 to -55F) will have an effective shelf life of 10 to 15-days.

As for the dough that you have, you might try reballing it and allowing it to cold ferment over night, then remove from the fridge and allow to set AT room temperature until the internal dough ball temperature reaches 60F, then open into skins and try making a pizza.

Without seeing what you actually did I can't comment on much.

[Re: How badly did I Screw up?](#) **513**

Why are you using such warm water for both the poolish and the dough? You should be targeting not more than 82F for the poolish (actually I like to target 75F) and 75 to not more than 80F for the finished dough temperature. I don't look for a "mature poolish, instead I go by the flavor I'm looking for which I typically get in about 8-hours. If your poolish is much warmer than 80F I would think it would be a candidate for full collapse by 14-hours. You still want to see some activity in the poolish. Hopefully your salt is 13.7-grams and not 113.7-grams (typo?). After the bulk fermentation I would just scale and ball and CF overnight, you will need to experiment to see how long you will need to allow the dough balls to set at room temperature before opening, with your absorption I'm guessing maybe 90-minutes?

[Re: Help with poolish dough recipe](#) **514**

Your dough formulation needs either diastatic malt or sugar if you are going to use "00" flour in a home oven. Your pizza is super limp and is severely lacking in any crust color. Both diastatic malt and sugar will provide crust color and might also help with yeast performance too. If it were me, I'd be using just a quality bread type flour that is already malted at the flour mill, I think you'll find it to be much more compatible with your home oven. "00" type flours typically perform best when

you can bake on the north side of 750F/399C.

[Re: Very airy dough](#)**515**

So you're using a "dough box" as opposed to a "pizza box"....got it!

When one opens a dough ball into a skin the dough ball is transformed either manually or mechanically or by a combination of both methods into a flattened shape known as a dough skin aka pizza skin upon which the sauce, cheese and other toppings are placed immediately before being placed into the oven for baking.

Since you were using a dough box, in the future should you have a change in plans all you will need to do is to lightly oil the dough balls (you can do that without disturbing them in the box unless they have already begun to proof (rise), in that case you might want to re-round the dough (flatten and reform back into dough balls), then lightly oil and place back into the dough box, leave the lid off for the first 2-hours when you put them into the fridge to ensure consistent cooling, then cover the box for the duration of time in the fridge. If you don't have room in the fridge for the dough box refer to my previous instructions for bagging the dough balls. If you don't leave the dough box open for those 2-hours the dough will not cool properly and can result in an over fermented dough condition by the time you're ready to use it (it would depend upon how much fermentation the dough balls had already received at the pizzeria), you will also experience a wet, sticky dough when you go to use the dough due to condensation forming inside the dough box as a result of not leaving it open. Some of that condensed water will be absorbed into the dough and can manifest itself later on in the form of bubbles forming on the dough during the baking process.

[Re: Crust on Dough?](#)**516**

Actually, the Farinograph report will not give you the information that you are looking for. The Farinograph absorption is that amount of water needed to be added to the flour to give a dough with a specific viscosity a full development. It serves only as a reference point by all who use it. To make application of the Farinograph absorption data one needs to develop what is called a Farinograph factor which is specific to the product being made. For example most U.S. commercial bakeries producing white pan bread will use a Farinograph factor of about 1.04 to possibly as high as 1.07. This means that for their specific product, made by their specific bread making process and equipment they will multiply the Farinograph absorption by 1.04 to 1.07 to get the STARTING dough absorption for that specific lot of flour, they will then make adjustments as necessary to the actual dough absorption for optimum processing and finished product quality characteristics. Because MAXIMUM dough absorption is specific to the product as well as the dough management process being employed the only real way to determine it is to make a series of dough with increasing dough absorption values until you find the HIGHEST absorption that the dough will carry while still allowing for decent handling properties and providing the desired finished product characteristics. Once you have done this you can divide that number by the Farinograph absorption value of THAT SAME FLOUR to find YOUR Farinograph factor, now with your Farinograph factor you can take any other flour for which you know the Farinograph absorption value and calculate the STARTING MAXIMUM dough absorption for that flour in YOUR shop.

You cannot calculate MAXIMUM dough absorption on just the protein level of the flour, there are just too many variables with the protein which include strength characteristics of the protein and especially the fermentation tolerance characteristics of the flour, and to some extent how the flour was milled can also

impact the absorption properties too, for example, if there is more starch damage in the flour it will exhibit a greater dough absorption than a like flour with a lower level of starch damage BUT with fermentation the damaged starch will be quickly hydrolyzed into sugar, thus releasing its water and the dough will turn to soup.

[Re: Best hydration / protein percentage](#) 517

It is called desiccation, to put it another way; your dough balls dried out. So, how do you prevent it from happening again? Simple, just very lightly oil the dough balls and place them into individual plastic bags (like bread bags). DO NOT use the ZipLock bags. In a pinch you can even use those thin bags that you can get in the produce department at your local supermarket. Drop the lightly oiled dough ball into the bag, twist the open end into a pony tail and tuck it under the dough ball as you place it into the fridge. To use the dough on the following day, remove the dough from the fridge about 90-minutes before you want to open it into skins, then turn the bag down around the dough ball and invert the bag over a floured work surface the dough will fall from the bag inverting it as it falls free. Flour both sides of the dough and begin opening it into a skin by your normal method. Something you said though sounds strange, you said the dough was in a regular pizza box (2-inches high at most). Mighty small dough balls?? Am I missing something? I'm assuming the dough was not already opened as you mentioned "dough balls", with several in the same box.

[Re: Crust on Dough?](#) 518

Amen to that!! ^^^

It's not just the yeast, but the combined effects of acids (produced during fermentation), and enzymes on the starch and proteins which work to degrade the starch and proteins making them more digestible plus the degraded proteins are further degraded during baking which helps to further contribute to the flavor of the baked crust.

If you want to see what a short or no fermentation dough tastes like just buy some commercial (Rich's) frozen dough and make a pizza skin out of it, dress it and bake it. Commercially made frozen dough is produced with essentially no fermentation but it does have the added additional yeast needed to allow it to perform much like an emergency dough.

[Re: Very airy dough](#) 519

I'm betting a cheap Walmart or Costco run of the mill toaster oven would work just fine for your limited application. I've made pizza a number of time in my son's afore mentioned toaster oven with decent success with thin crust pizzas. I haven't tried making anything close to a deep-dish or even a thick crust pizza in it so I can't comment.

[Re: Black & Decker 5 minute pizza oven + steel? Indoor pizza oven?](#) 520

Any yeast calculator that doesn't take temperature into consideration is NOT a calculator. Temperature is the #1 driver of fermentation/yeast activity. There is no way one can calculate the amount of yeast to use without first knowing the temperature that the dough will be fermented at.

[Re: Very airy dough](#) 521

Spot on! ^^^

Normally malted flour has approximately 0.25% 20 degree L dry malt powder. So if you have a 60 degree L malt powder you would use 1/3 as much 0.25 divided by 3 = 0.0833333% to achieve that level of malting. There is nothing chiseled in stone

regarding how much malt to use but if you use too much the first thing you will notice is a sticky dough condition, then excessive crust color development during baking and if you really go for broke you might even experience a weakening of the dough accompanied by the stickiness.

Tom Lehmann

[Re: Diastatic Malt - How to adjust for different Lintner strengths?](#) 522

Not a bad looking pizza at all. See, that wasn't so hard after all, was it? :chef:
:drool:

You're well on your way to making even more great pizzas!

[Re: NY style in electric deck oven](#) 523

Always before. This results in less damage to the yeast during the freezing process.

[Re: Freezing dough question](#) 524

It doesn't do any good to put them back into the cooler as it is all but impossibly to effectively cool them once they have fermented and become less dense, but all is not lost, I NEVER find it necessary to toss out any unused dough balls.

1) They can be incorporated into new dough at up to 15% of the new dough weight.

2) The dough balls can be partially opened, placed on screens and stored in the cooler in a wire tree rack (cover with a food contact approved bag after 20 to 30-minutes).

3) Make into bread sticks or garlic knots.

4) Make into dessert pizzas by opening into skins, brushing with melted butter and sprinkling with a cinnamon-sugar mixture, then make a cheese base (1# cream cheese, 1# sour cream, 1# ricotta cheese, 8-ounces powdered sugar, 2 whole eggs (about 100-grams/4-ounces) and mix until smooth, add cream to thin if necessary, you want the consistency of mayonnaise. Spread about 3/16-inch over the skin leaving a 1/4-inch edge exposed. Top with sliced fruit, berries, sliced grapes, etc. If you wish you can also use drained fruit cocktail. Bake just like your regular pizzas and finish with a powdered sugar and water icing drizzled over the top after cooling for about 15-minutes. Store under refrigeration. Serve lightly reheated or cold. We have discussed this dessert pizza before so a search through the archives should bring it up with more detail.

If you are so inclined you can also just stop after applying the cinnamon and sugar, sprinkle with a ready made streusel mix and bake the same as your regular pizzas. Cut into strips or squares and serve with a side cup of powdered sugar-water icing as a dessert option.

Use your imagination to come up with ways to drive your business with what you have been tossing out.

[Re: Dough resting at room temperature before tossing](#) 525

Alex, that's a hard question to answer without knowing a lot more about your oven, but for starters I personally start at the highest temperature your oven will bake at (both top and bottom the same) and let the chips fall where they may regarding the total baking time. Use the bake characteristics to guide you in making further temperature adjustments if necessary.

[Re: NY style in electric deck oven](#) 526

White flour:

Room Temperature storage in metal or plastic containers (5-gallon pails) = 1-year.
Refrigerated storage in plastic bags or plastic pails = 2+ years.

Frozen in plastic bags placed in plastic 5-gallon pails and sealed = 10-years +.

Whole-wheat flour: Room temperature = 2 to 3-weeks (rancidity is the issue).

Whole wheat flour: Refrigerated: 4 to 6-months.

However you store the flour it is suggested that you break it down into quantities that you can use in 2 or 3-weeks so you will be putting multiple bags into a plastic pail, then you can remove just what you need for a few week use without disturbing the rest.

Things to look for: 1) The flour clumps. Flour doesn't clump, this is caused by an Indian Meal Moth infestation and it is their webs that result in the clumping. 2) Flour beetles or cigarette beetles can infest flour and are seen as what looks like coarse black pepper in the flour (usually at the top of the bag).

Whole wheat flour: Frozen 8 to 12-months.

NOTE: If you freeze the flour always break it down into smaller bags for use over a week or so. Don't use flour directly out of the freezer, instead allow it to temper AT room temperature for 24-hours before opening the bag. This will prevent condensation from forming in the flour left in the bag which can lead to mold development in the flour.

Pick your poison.

[Re: how long will flour stay good for?527](#)

I'll give it 5-years....on the outside, my gut instinct says 3-years.

Burn out is the biggest obstacle.

[Re: two man pizza shop ?528](#)

Welcome! You came to the right place to up your pizza game!

I'd suggest that you begin by researching some of the past discussions on cracker type thin crust pizza. We have had some very good discussions along with instructions for making it that might help you get started, then let us know where you need help. Just for a reference, you say you eat mostly chain pizza, which one has the crust closest to what you would like to make, someone here might have already reverse engineered/replicated it already for you.

[Re: Looking to make great Pizza at home !529](#)

Oxygenate the flour? You're pulling my leg, right? :-D :-D :-D

[Re: How to use a spiral mixer530](#)

I don't think it's the cold fermentation that is the problem but instead I think it's all the extra time you are giving the dough before opening it. By nature, sourdoughs are more acid than other types of doughs and acids degrade proteins (it is the two gluten forming proteins that create what we fondly refer to as "dough") all that additional time in the fridge is just allowing that much more time for the acids to further degrade the flour proteins which results in the weak dough that you're experiencing.

[Re: Trouble with sourdough cold ferment531](#)

You use a spiral mixer just like any other dough mixer, add tempered water first, followed by the flour, salt, yeast, sugar (if used) and any other dry ingredients, mix at low speed just until all of the flour is whetted, then add the oil while mixing at low speed for 1-minute and finish mixing at second or high speed just until the dough takes on a smooth appearance.....you're done mixing.

[Re: How to use a spiral mixer532](#)

The one question that just begs to be asked is: What is your business concept?

[Re: two man pizza shop ?](#)**533**

leto;

Your assumption is indeed correct.

[Re: Par baking pizza temperature](#)**534**

I use a KD-8000. It has a sufficiently large platform and plenty of capacity (remember capacity = weight of container + contents), and it runs on regular flashlight batteries, for a very long time I might add. Cost is about \$50.00.

[Re: Scale to get started](#)**535**

Since all chicken, like eggs are considered to be E-coli positive I am more concerned over cross contamination than being able to cook it to 160F (the industry accepted target temperature).

[Re: Raw chicken?](#)**536**

What is being described sounds a lot like a high starch damage flour.

Carries high absorption beautifully due to the damaged starch but exhibits only about 90-minutes of fermentation tolerance after which time the dough "lets-down" flattens out.

How do the dough balls look at 1 and 2-hours?

[Re: W380 soup](#)**537**

Thanks guys, I really appreciate it!

[Re: Welcome Back Tom \(Dough Doctor\)!!!](#)**538**

While CY may be more "sexy" to use the IDY, when used properly, will give you much more consistent results and it has a significantly longer shelf life too.

[Re: Preferred Yeast](#)**539**

Thank you,

[Re: Welcome Back Tom \(Dough Doctor\)!!!](#)**540**

ZULU202;

If you will contact me directly at <thedoughdoctor@hotmail.com> I'll send you a copy of my dough management procedure which should put you on "terra firma" and from there you can experiment as you wish.

[Re: Confused with different ways of making dough](#)**541**

Does the flour carry the water initially?

How are you mixing the dough? What does the dough look like after mixing? After 12-hours? After 24-hours?

More information is needed.

[Re: W380 soup](#)**542**

Aluminum sheet pans work well too, place the dough balls on a litely oiled sheet pan (18 X 26") and cover with a food contact approved plastic bag. I just wrote an article on this for PMQ Magazine, it will be in the second part of a two part article. The first part is discussion on how to use dough boxes.

[Re: Cheap dough tray in UK](#)**543**

::) ::) ::) ::)

[Re: Pizza crust on drier side](#)**544**

You did ask for a finished crust akin to a P.J.s, that's pretty close! To reduce the crust browning just reduce the sugar until you get the color you're looking for. For a more open crumb structure reduce the dough mixing time by 2-minutes and increase the total yeast by 1%, let's see where that gets us.

[Re: Creating something new and standardised](#).**545**

::) ::) ::) ::) ::)

[Re: Dough too soft/limp \(before cooking\) after 4 day rise?](#)**546**

Potato starch is nothing more than finely ground dehydrated mashed potato, so if you have potato starch go ahead and use it.

[Re: Pizza crust on drier side](#)**547**

Yael, "core", like the core of the earth. :-D

[Re: 24hr Bulk Cold Ferment done....now what? Something normally goes wrong here](#)**548**

They're not harmful and they will go away during baking, nothing to worry about. Pretty common.

[Re: What are black spots in dough?](#)**549**

To match the equivalent of flour that is malted at the mill you will need to use 0.25% of a 20L diastatic malt powder with an un-malted flour.

[Re: Where can diastatic malt be found?](#)**550**

Your ADY amount is 0.6%, not 0.006% (3 divided by 500 X 100 = 0.6)

That's a lot of yeast for the way you are fermenting the dough. Plus I don't advise allowing the dough to come up to room temperature after the cold fermentation period, instead, allow it to temper AT (NO TO) room temperature until the internal ball temperature reaches 60F.

[Re: 24hr Bulk Cold Ferment done....now what? Something normally goes wrong here](#)**551**

By my calculation you are trying to make a 4-day dough using 1.69% IDY (0.2 divided by 11.8 X 100 = 1/69491%) This is WWAAYY too much IDY. For a 4-day dough I only use 0.375% (11.8 X 0.375 (press the "%" key) and read: 0.04425-ounce(1.2567-grams).

[Re: Dough too soft/limp \(before cooking\) after 4 day rise?](#)**552**

Deck ovens have their limitations. The more pizzas you put into the oven the longer and more often the door is open/opened thus reducing top heat. With Marsal deck ovens they have tremendous heat recovery in the deck which is why the bottoms are getting too dark or burned. I also know their advertising that you don't need to rotate pizzas in their ovens, great advertising claim, and it works with just one or two pizzas in the oven, with more pizzas than that, don't believe it. Without knowing your dough formula and dough management procedure, I feel you may be out of oven capacity. Your baking time is not too out of line with what we have found when baking with a full deck of pizzas.

Can you make your pizzas bake any faster? Maybe but we need to know where you are presently at with dough formulation, scaling weight and dough management as you may need to make changes to all of these.

[Re: I need some help altering my dough recipe to cook at a higher](#)

[temperature.553](#)

If it is a softer crumb structure that you are seeking you can increase the fat content up to about 8% without any difficulties. The only thing that increasing the dough absorption will change is the handling properties of the dough as any additional water will just need to be baked out (it is very difficult to increase the moisture content of the crumb by a significant amount without adding something to retain that additional water. So, if you want to have a more moist crumb your best bet will be to include some mashed potato flakes in the dough formula. I would suggest starting at 2% and going up in 2% increments from there. For every 1% mashed potato flake that you add you will need to increase the dough absorption by an additional 2%.

If you want to know what is in the "additive cocktail" that you are using all you need to do is to look up the E.U. numbers shown in their ingredient listing and that will identify the functional ingredients. Depending upon what is actually included you might be able to eliminate it but we would need to know the constituent ingredients before making a decision. In many cases I've found that when cocktails such as this are used the cost will exceed the benefit by a significant margin. I'm betting that included in the ingredients are salt, sugar, DATEM, ascorbic acid and some type of a fat to eliminate dusting and separation.

[Re: Pizza crust on drier side554](#)

Regarding the soda, if there is any oil/fat of any kind in/on the stone the soda will saponify the fat rendering a soapy taste which could make matters even worse.

[Re: What does a Pizza Stone supposed to smell like? Is mine bad?555](#)

Yes.

[Re: How do I modify my pizza making if I have active dry yeast for bread machines? 556](#)

If you can smell it, it's volatile, if they're volatile you should be able to place your stone in the oven and cook-off the volatiles. Try placing your stone in the oven at pizza baking temperature and let it bake for an hour or more, if you have a broiler maybe put it in or near the broiler heat. This should drive off any volatiles. You mentioned soap, did you ever wash it with soap? I never wash mine, ever! If it really needs cleaning (seldom) I just scrape it and if deemed necessary I might hit it with a little sandpaper. Just to confirm though, this is NOT a glazed ceramic tile we're talking about..right?

[Re: What does a Pizza Stone supposed to smell like? Is mine bad?557](#)

Non-diastatic malt is often considered as a sweetener or type of sugar but with a flavor component added to it. Due to the flavor component it is not a good sweetener if you are trying to achieve a sweeter tasting baked product but if you are looking for a "nutty" flavor aspect or a malted milk type flavor (depends upon the amount you use) or a darker crust color, look no further.

[Re: Where can diastatic malt be found? 558](#)

Previously answered in response to your email.

[Re: NY Style with spiral mixer559](#)

I think 5% additional dough absorption would be a good place to start. For all practical purposes, there is NO difference in performance between CY and IDY or

even ADY for that matter when each is used at the correct substitution level. IDY will provide overall more consistent performance than CY and it also has a much longer shelf life. A good many of us here have transitioned to IDY. I for one, can't even tell you when I last used CY.

[Re: help finding a homemade "philly cheesesteak" bun/roll recipe](#) 560

There's your problem. If the flour is NOT malted in some way at the mill you need to bake your pizzas at temperatures over 750F/399C if you expect to get any crust color on your pizzas.

All is not lost though, you can either add a small amount of diastatic (enzyme active) malt (about 0.25% of a 20L diastatic malt powder, if you cannot get that let us know what you have access to and one of use here can tell you how much to use. You can also just add some sugar to the dough formula. At your oven temperature I'd suggest 3% sugar for starters to see if that gives you a decent crust color.

[Re: Please help my white pizza bottom!! Should I consider a baking steel/stone?](#) 561

One other thing, it looks like the final proof was too dry and or the dough absorption was too low for your specific flour.

[Re: help finding a homemade "philly cheesesteak" bun/roll recipe](#) 562

Not too bad for the first horse out of the gate. :)

The next time you make them form them with blunt ends and allow to final proof for a longer time.

Here is the correct way to form them:

Form the dough piece into a rectangle about 10-inches wide and 1/4-inch thick, fold the two ends so they just touch in the middle, and roll up like a jelly roll, set aside (seam side down) to rest for a few minutes, then roll them under your palms to 8-inches in length, place onto pans for final proofing with the seam side down.

Note: If the dough doesn't roll well LIGHTLY dampen the work surface with water and lightly moisten your hands. Like everything else, practice will make perfect.

[Re: help finding a homemade "philly cheesesteak" bun/roll recipe](#) 563

The main factors are:

Maximize dough absorption.

Optimize dough fermentation.

Open the dough into a skin by hand and do it properly.

Correct baking temperature for the type of crust being made.

[Re: Cornicione](#) 564

The top crust doesn't look like it has much color either. Are you using a "00" flour?

[Re: Please help my white pizza bottom!! Should I consider a baking steel/stone?](#) 565

Re-read.. "immediately before you place it in the oven".

[Re: help finding a homemade "philly cheesesteak" bun/roll recipe](#) 566

"Purdy, purdy, purdy"! :drool:

Try mixing at low speed to incorporate the ingredients for about 2-minutes, then go to the next higher speed for the actual development of the dough. Be sure to mix the dough to a point where its "JUST" beginning to take on a smooth appearance.

[Re: Hand mixing vs Commercial mixer](#) 567

Warm water? Hand warm water ???

In all of the testing that we did with our students we found that "hand warm" water was actually too warm/hot. Your skin temperature is just under 98.6F so "warm" would be even hotter. Typical dough water temperature is around 75F. There is a possibility that your dough temperature is too hot which results in a sticky dough condition at the very least. Time to break out the old thermometer. :-D

[Re: My dough burnt, why?](#)**568**

Let us know how it turns out with the higher yeast level. Be sure to make a few diagonal "French" cuts across the top of each bun immediately before you place it in the oven as this will allow for more uniform expansion of the dough, especially with the high yeast level.

[Re: help finding a homemade "philly cheesesteak" bun/roll recipe](#)**569**

IDY does need to be per-hydrated when the dough is to be mixed by HAND, but it is not necessary when the dough is to be mixed by MACHINE. Also, IDY does not need to be activated as ADY does. Notice that I said to suspend it in a small portion of 95F water, as soon as the yeast is suspended it can be added to the dough water (you don't need to wait 10-minutes to activate the IDY as you do for ADY)

Details, details, details! :-D

[Re: How to get consistent](#)**570**

Ditch the "eyeballing" suspend the yeast in a known quantity of water and subdivide. For example, if you want 0.5-gram of yeast just put 1-gram into 99-grams of water (95 to 100F) stir well to suspend the yeast, then measure 50-grams of the suspension and you will have something very close to 0.5-gram of yeast. Be sure to include the water in the suspension as part of the total dough water.

[Re: Trying to Tweak An "Ultimate Pizza Dough Recipe"](#)**571**

NO! Use IDY at only 40% of the CY amount (weight). To use the IDY just add it dry right on top of the flour.

[Re: help finding a homemade "philly cheesesteak" bun/roll recipe](#)**572**

What kind of mixer are we talking about? A picture of the mixer and mixing attachment would be helpful.

Also, how are you mixing the dough? Speed and time? What is the finished (mixed) dough temperature?

[Re: Hand mixing vs Commercial mixer](#)**573**

From what is being described, I have only seen something like this once before and it was the result of a very hot and weak dough.

We really need to see your dough formula and dough management procedure and be sure to include the dough temperature after mixing and at points along the way. If your dough is getting to a temperature of 90F/32.2C or more at any time this would validate the above as a potential cause.

[Re: Crust Full of Air](#)**574**

First of all, it doesn't appear that you are suspending the IDY in a small portion of 95F water prior to addition to the dough. Second, you don't say if you are covering the container when you place it in the fridge (you should oil the top of the dough and leave it UNCOVERED until the internal dough ball temperature reaches 50 to 55F (I normally target 50F, just be consistent with the temperature), after the dough ball reaches the targeted temperature cover it and kiss it good night. When

removing the dough from the fridge you should leave it in the fermentation container (still covered) and allow the dough balls to warm to 55 to 60F (internal dough ball temperature) before opening them into skins.

Try these changes to your process and let us know if you see any improvement.

[Re: How to get consistent](#)**575**

While some will use a "bubble popper" to deflate the bubbles as they begin to form (my bubble popper is nothing more than a piece of 6.5-mm diameter aluminum rod with a 90 degree bend on one end leaving a 50-mm leg which I ground a point on, the other end is bent into a "U" shape to form a handle). Most pizzerias will have one of these hanging near their oven for use just in case a bubble might get out of hand. Some will also address the bubble issue from a dough formula/dough management procedure aspect. In your specific case, while you didn't provide any information on actual dough temps, I tend to agree that the issue might be due to an over fermented dough condition. To test this theory make another dough using a 25% reduction in total fermentation time. To do this just reduce the fermentation time by 25% at each of the fermentation stages. If you see an improvement you can fine tune the fermentation further, if not we will have to look at things from a different perspective but we'll need to know what the dough looks like after each fermentation stage as well as internal dough temps from mixing until you're ready to open the dough into skins for dressing.

[Re: Air bubbles to big](#)**576**

There are those here that might be willing to do a DIY home root canal for those characteristics! :-D

But since you asked;

Mix the dough for an additional 3-minutes.

Reduce the dough absorption by 5%

Reduce the yeast by 25%

With these changes you should see more of a bread like crumb structure in your finished crusts.

With all of that said, it would help to know what your present dough formula and dough management procedure is, but lacking that information give the above a try and let us know if you see any improvement.

[Re: Crust Full of Air](#)**577**

I've also got a good Hoagie bun formula and procedure posted in the Recipe Bank at the PMQ web site <www.pmq.com>.

[Re: help finding a homemade "philly cheesesteak" bun/roll recipe](#)**578**

In preparation for your experiments to improve your pizza I would highly suggest that you first purchase a good electronic scale that can be used to weigh your ingredients allowing you to convert your "recipe" into a dough formula based on actual weight measures as opposed to volumetric portions. Also pick up a simple dial/stem type thermometer as it will come in handy for setting your water temperature and measuring dough temperature. With these two handy tools you'll be ready to have fun getting the finished pizza characteristics that you're looking for.

[Re: Trying to Tweak An "Ultimate Pizza Dough Recipe"](#)**579**

The stickiness was most likely the result of the hand kneading process which resulted in an under mixed dough condition. You might try using an autolyze made with all of the water and 75% of the flour. Allow it to hydrate the flour for 1-hour

and then add the remainder of the dough ingredients and begin your hand mixing and kneading process.

Without knowing more about your dough formula and process that's about the best advice I can offer for now.

[Re: My dough burnt, why?](#)**580**

Additionally, while the yeast may be semi-dormant in the fridge the flour is still being subjected to the by-products of fermentation (think of like marinating a tough cut of meat) which will have a profound effect upon the dough and crust characteristics after the cold fermentation period. For most of us, we are cold fermenting our dough to achieve certain desired characteristics but we are not typically fermenting the dough to a point where failure is imminent with a little additional fermentation or if the finished dough temperature is a little off the mark so while an additional day in the fridge won't usually result in a catastrophic failure of the dough it certainly will affect some of the dough and finished product characteristics, just not to the point where an unacceptable pizza was the end result.

[Re: Guaging Fermentation](#) **21**

What kind of flour are you using?

What is your dough formulation?

[Re: Noob question...orange oil on cheese?](#)**22**

It's not the fat that retains the gas in yeast leavened dough systems be it for bread or donuts, all the fat does is lubricate the dough for ease of expansion and coat the individual cells for better gas retention. In making butter cream icing as well as many types of cakes the fat does play an important role by entrapping air to provide a nuclei for the crumb structure development, but not in yeast leavened products, not even in sweet dough which can contain as much as 24% fat. Just for the record, low ratio cakes will typically contain fat (as a plastic fat) at an amount at least equal to that of the flour or 100%.

[Re: on fat : oil, margarine, vegetable shortening, butter](#)**23**

Since there is no real way of knowing the strength of it I'd suggest using it at maybe 10% and start out with 0.1% IDY addition and make the necessary corrections from there.

[Re: Using A Lievito Madre Plus Yeast](#)**24**

OK, if you say so. We will always make the best product using that which we have the greatest confidence in. :chef:

[Re: Is high gluten flour necessary for a pizzeria pizza dough recipe?](#)**25**

Yael;

I used to do that myself when handling extremely high absorption doughs but changed over to using a little oil on my hands years ago.

[Re: Dusting the ball with flour vs. water](#)**26**

PizzaCalcio;

In what way is spring wheat flour a lower quality flour? Just curious as to what your thoughts are.

[Re: Is high gluten flour necessary for a pizzeria pizza dough recipe?](#)**27**

How old is the starter? Under what conditions are you storing it?

[Re: Using A Lievito Madre Plus Yeast](#)**28**

No, high protein (13 to 14.5%) flour isn't necessarily needed in a commercial pizzeria environment. Your decision on flour protein content will depend upon the following:

Type of pizza you're making.

Type of store (DELCO or dine-in or both)

How long you want to hold the dough for and under what conditions.

The dough management procedure you use.

The manner in which the dough will be opened into a skin.

One type of flour that I never recommend for use in a pizzeria is all-purpose flour (AP flour), the reason for this is because there is no one accepted identity for all-purpose flour. Because of this it can be made from a blend of strong wheat varieties giving it the performance properties of a pretty decent bread type flour while at the same time other manufacturers see it differently and make it from varieties of soft wheat or even a blend of hard and soft wheat varieties. The fact is that if you buy an AP flour from one manufacturer it may or may not perform the same or similarly to that from another manufacturer. Flours that are sold as "bread" flour have an intended purpose (to make bread) and all of the milling companies mill their bread type flours to be very similar to that of their competition so if you had to change suppliers (like that has NEVER happened) you wouldn't see much, if any, change in flour performance. Once you enter into the realm of "bread" type flours there are flours of different strength and these are differentiated by their protein content with the lower protein content flours being the weaker (10.5 to 11.8%) and the higher protein content flours (13.4 to 14.5%) being the strongest. Right in the middle you have the flours with 12 to 12.8% protein content which many (myself included) look at as being a good, all around pizza flour. You can go with a higher protein flour but you will pay more for it and you should have a specific reason for using it (like a New York style pizza which is chewy) or if you will be a DELCO operation chewy is a bad word so by opting to use a lower protein flour in the 10.5 to 11.8% protein range you can reduce some of the chewiness.

[Re: Is high gluten flour necessary for a pizzeria pizza dough recipe?](#)**29**

The main byproducts of fermentation that we're concerned with are carbon dioxide, alcohol and acids (acetic, lactic and propionic) plus the necessary time for amylase and protease enzymes to do a little of their magic too. All of these combined, give us a finished dough with specific handling properties and a finished (baked) crust with certain targeted flavor and physical characteristics that we are trying to achieve. While many dough recipes and formulas do say to allow the dough to "double in size" this can be hard to ascertain in view of the wide range of dough absorption that can be employed in making the dough, for example, a 70 or 75% absorption dough will not visually look the same after "doubling in size/volume" as a 55% absorption dough would. What you are proposing I think would be assuming that a colder dough, if allowed to ferment long enough to double in volume would be the same as a warmer dough that has doubled in size (maybe I'm wrong on that?) but the truth is that the colder dough would be different from the warmer fermented dough even though they are both at the same volume, the reason being that the colder temperature has slowed or stopped the enzymatic activity and the ratio of those three main acids of fermentation will have changed which results in a different finished product flavor profile. I think it would be safe to say that there are just too many different things happening during the

fermentation process to go by the volume of the dough alone.

[Re: Guaging Fermentation 30](#)

If slimy is less sticky....OK? In my world a little dusting flour makes my dough feel a lot less sticky than water and what are you going to do with a wet, slimy dough ball, aside from making a giant dumpling out of it?

The change in the % dough absorption is easy to calculate with either dusting flour or "water". Just weigh the dough ball before putting it into the dusting flour or water, then weigh it again after putting it into the dusting flour or water, this will give you the weight gain in of the dough ball due to the flour or water. Now, divide the dough ball weight by the sum of the total bakers percent after dividing it by 100 (easy to do by just moving the decimal place two places to the left). This will give you the flour weight in the dough ball. Lastly, divide the dough ball weight gain by the flour weight in the dough ball and this will give you the percent increase in absorption for the water or add it to the flour weight and divide the dough absorption percent by the new flour weight to find the impact on dough absorption that the added flour weight had.

Aren't you glad to didn't sleep through math class? :-D

[Re: Dusting the ball with flour vs. water 31](#)

If you will search back in the archives for discussions on biochemical gluten development it will help you understand gluten development. I used to teach home pizza making to residents here in Riley County, KS on weekends during the summer months. The only tools that were needed to make the dough were a suitably sized bowl and a wooden spoon. We mixed the dough using just a wooden spoon (has to be wooden) this way everybody knew when to stop mixing (when one was in fear of breaking the spoon it was time to stop mixing). The dough was then scraped out of the bowl onto a lightly oiled counter top, it was pulled and stretched just a couple of times to allow it to be formed into something resembling a ball, this was then placed back into the bowl which had been lightly oiled, a piece of plastic (Walmart bags were pretty commonly used) was placed over the container to prevent drying, the dough was allowed to ferment for 90-minutes, it was then turned out of the container onto a lightly dusted surface and kneaded/stretched just a few times (less than a minute) and placed back into the container to continue fermenting for another 90-minutes, the dough was then turned out of the container again and cut into four pieces, each piece was gently formed into a ball (care was taken so as NOT to stress the dough. The dough balls were covered with the same piece of plastic that was used to cover the fermenting dough and allowed to rest for 30-minutes, each dough ball was then opened into a skin by demonstrated methods (rolling pin/pastry pin/hand stretching), they were then dressed and baked in the home oven that was available in the host's kitchen. Everyone was amazed at how easy it was to make the dough (NO STRENUOUS KNEADING) and no watching the clock as all of the fermentation periods are VERY flexible so it's something that can be done on the side while you're busy with other things in your daily life.

For toppings I asked each participant to bring with them anything from hot dogs to hamburger to left overs in the fridge. This gave them the ability to use pizza as one might think of hash (a place to use left overs). At the end of the session there wasn't a bad pizza, nor a hungry person in the group.

Too many time we over think the process of making pizza and become intimidated by our own thoughts, as you can see from the above process it really isn't that difficult to make a basic pizza. Once you have mastered the basic pizza you can then branch out and explore making other types of pizza by different and more involved dough making processes. Remember the evolutionary progression of

learning to sit, butt scoot, crawl, table surf, walk, trot, run but only after that can you branch out into long jumping and pole vaulting. Making pizza follows a similar progression, hopefully on a faster track. :-D

[Re: Coach my \(non-existent\) kneading skills.](#)32

And then there's the 5-second rule.

For those who don't know what that is:

If no one is looking and you can pick it up off of the floor in less than 5-seconds it never happened. >:D >:D >:D

[Re: Small batches](#)33

For us its sweet basil, tomatoes, bell peppers, sweet banana peppers, chives, and our staples are potatoes, snow peas, radishes, Blue Lake beans, beets, turnips, and Swiss Chard (all grown for the greens) and our winter favorite butternut squash.

With the exception of the snow peas and squash everything is grown in large plastic tubs that once held calf starter feed. Our driveway is a little over 90-feet in length and I have one entire side of it lined with the growing tubs and in addition we have a fenced off garden area in the back yard. If you add in our gooseberry and blackberry bushes, apple, peach, pear and apricot trees along with a couple of deer that I take every year we are pretty self sufficient food wise.

Because we do essentially all container growing the garden is really easy to care for and to harvest from, but then there's all the preserves to make and fruit to dry and that alone will take almost 6-weeks out of our lives every year. In the winter though it's nice to sit back and enjoy that summer and fall harvest while watching the snow fall, knowing that as soon as it stops I'll be out plowing our cul-de-sac and neighbor's driveways.

When you get to be 78-years old you've got to look for things do to keep out of trouble! ;D

[Re: Which herbs/vegetables are worth growing?](#)34

Scottr;

Yup, there's your answer. ^^^

[Re: How many times do you reuse your frying oil?](#)35

When we were doing research on dough we were always hesitant to use doughs made with less than 500-grams of flour weight because they were difficult to scale accurately, did not interact in the mixers in the same manner as a larger sized dough did and only provided a single test sample (you need at least 3 samples per batch to have any confidence in the results you're getting), and that is why I'm not a fan of making very small size doughs.

[Re: Small batches](#)36

First off, why such a small dough size? Go with a dough sized 5 to 10 times that size. It looked more like you were trying to ball the dough than to knead the dough. The larger size dough will be a lot easier to knead than such a small dough. Consider this, you mentioned "mixing" the dough so it sounds like you have a dough mixer. Normally the dough is not kneaded after mixing but if you want to it only needs to be kneaded for a couple of minutes, not 10 minutes as I heard mentioned. With the larger dough size you can let the weight of the dough ball work for you or you can practice bench kneading the dough, this is where the dough is placed onto the bench and pulled/stretched then laid back upon itself numerous times, there are some good videos I'm sure, which will demonstrate this method of kneading.

You really need to make a bigger dough to practice kneading ;D
[Re: Coach my \(non-existent\) kneading skills](#)**37**

Keeping the fat clean does help but I'm betting that the length of time the fryer is used has more to do with it. If you fire up the fryer and leave it at 365F all day long the fat will tend to go rancid faster than it would if you just fire it up to use it for an hour or so each time. The actual type of fat also plays a HUGE part in determining how fast the fat will go rancid.

[Re: How many times do you reuse your frying oil?](#)**38**

Dough absorption is ALWAYS based on just the water, never the water + oil. The oil should always be shown in the dough formulation as an ingredient percent based on the weight of the total dough flour aka bakers percent. With that said, since oil is a liquid it will possess the ability to alter the viscosity of the dough at high levels, for this reason we will take into account the amount of oil being used in the dough as an added ingredient when determining the dough absorption to be used.
Regarding your last sentence, I think that was in reference to making pizza using commercially frozen dough.

[Re: The reasons for different types of dough](#)**39**

The dough should feel "lively", as opposed to like putty but it should not have large gas bubbles in it either because these will manifest themselves in the finished donut too.

[Re: adding salt too early??](#)**40**

No, just mix the dough until it begins to take on a smooth appearance, the amount of mixing you put into the dough will have no impact upon the toughness/chewiness of the finished crust BUT it can/will impact how the dough handles. By the way, I've never had to proof a pan dough for more than about 75-minutes on the outside, most are in the 45 to 60-minute range. If I'm in a pizzeria where we're making a lot of pizzas we proof for only about 20-minutes and then take to the cooler where they continue to proof to the required height and then go into hibernation until needed, this way we can use them directly from the cooler. That's how P.H. used to make all of their pan pizzas at one time so it's not a new process. If your yeast level is too low it's possible that you can end up with a dreaded gum line just under the sauce which is why we don't like to manage fermentation by reducing the yeast level.

[Re: Replacing AP with All Trumps?](#)**581**

Proofing comes after the dough is placed into the pan, I think you are referring to fermentation?

The very first item on my list of suggested changes was indeed "longer fermentation " time.

Due to the higher protein content the dough will require a higher dough absorption and you will still need to allow the dough to ferment for a longer time to help "mellow" condition/break down, some of that protein, failure to do so will result in a dough that is tougher, more elastic and harder to work with. It will also exhibit more dough memory characteristics when you are trying to shape the dough to the pan. With proper adjustments to the dough formula and dough management procedure you can get your All Trumps flour to perform similarly to the 11% protein all purpose flour.

[Re: Replacing AP with All Trumps?](#)**582**

Absolutely! The temperature rise is due to the heat of metabolism resulting in a temperature gain of approximately 1F per hour.

[Re: Fermentation timing factors](#)583

Dough "recipes" based on volumetric portions such as teaspoons, tablespoons, cups, coffee cans, etc., typically have to be modified in some way when increasing or decreasing the size of the dough/recipe but dough "formulas" which are expressed in bakers percent and based on weight measurements such as pounds, ounces, kilograms, grams, etc., can be easily manipulated in size without any dough formulation changes. This is but one reason why the majority of pizza makers here work with dough formulas as opposed to dough recipes.

If you want to learn more about bakers percent I'm sure a search of archived posts will provide additional information, I've also written articles of the use of bakers percent too.

[Re: Doubling NY style dough recipe?](#)584

Stainless steel like the one in the lower right hand corner. DO NOT take the donuts off of the screen, instead place the donuts and screen all into the frying fat (about 100-mm deep, the donuts will float off of the screen on their own, then use your frying sticks to turn the donuts. If you put handles onto the screen you can just lift the screen out with the handles and the donuts come along for the ride, allow to dip for a minute (literally) and apply glaze to the donuts (they should still be so hot as to be unpleasant to hold in your hand).

[Re: on fat : oil, margarine, vegetable shortening, butter](#)585

Not that I'm aware of.

[Re: Fermentation timing factors](#)586

The A.T. flour is one of the highest protein flours we typically work with as it is 14+% protein content. Not knowing the protein content of your AP flour (the nutritional panel on the bag will give you a good indication of what it is) I can't be too specific on the changes but I would expect the following:

Longer fermentation time.

Increased fat level.

Increase in dough absorption.

More rest times or a longer rest time needed when fitting the dough into the pan.

[Re: Replacing AP with All Trumps?](#)587

A small amount of sugar will provide a very slight increase in the fermentation rate, but after that it will slow it down but sustain the yeast for a longer fermentation time.

[Re: Fermentation timing factors](#)588

IDY, ADY and CY all perform essentially the same when used at the correct substitution levels so there is no real difference between them. Many people prefer to use IDY due to its ease of use, long shelf life, and uniformity. Mixing times normally run around 8 to 10-minutes but this is HIGHLY variable and dependent upon the type of mixer being used as well as the type of agitator the mixer is equipped with.

Just mix the dough until it begins to take on a smooth appearance, that's all the mixing you need for a pizza dough.

[Re: Creating something new and standardised.](#)589

If you have ADY pre-hydrate and activate it prior to addition to the dough. Put the ADY in about 5 times its weight of 100F water (use a thermometer), stir to suspend the yeast in the water and allow to activate for 10-minutes, then stir well and add to the dough water, rinse out the container in the dough water too and you're ready to go.

[Re: How do I modify my pizza making if I have active dry yeast for bread machines? 590](#)

To replace ADY with CY use twice as much CY.

By the way, the ADY really should be pre-hydrated and activated in 100F water prior to addition to the dough to get the best performance from it. IDY can be added just like CY, just add it right on top of the flour as long as you are machine mixing, if you're hand mixing the IDY needs to be pre-hydrated in 95F water (no need to activate) prior to addition to the dough.

[Re: Active dry yeast vs fresh yeast ratio? 591](#)

I agree with Foreplease, that the dough balls needed more rest time. Whenever you encounter something like that just step back and give the dough more time, it will eventually relax and open very easily.

[Re: Over Worked Dough? 592](#)

I think I'll rack this one up to another "Don't believe everything you read on the internet". You use a fridge, at accepted refrigeration temperatures (34 to 40F) because you want to significantly slow the rate of fermentation to allow holding the dough in a viable condition for a period of time (hours to days). Due to the insulating properties of the dough placing it in the fridge will not just immediately stop the fermentation process like turning off a light switch, but it will significantly slow it allowing for gradual fermentation as well as time for the acids and enzymes associated with the fermentation process to work on the dough to develop flavor. The higher the storage temperature the faster the fermentation rate. A wine fridge at 50F WILL NOT slow fermentation as well as a refrigerator at 38F. This doesn't mean that a wine fridge cannot be used to store dough in, it certainly can, just like you can store the dough at room temperature if you want to BUT the dough has to be specifically formulated to allow for this, just like you have to specifically formulate the dough if you want to hold it at room temperature. One also has to be cognizant of the fact that when the dough is fermented at different temperatures you will get a different flavor imparted to the finished product. Remember that temperature is the "driver" of fermentation, all things equal, the higher the temperature the faster the rate of fermentation, that's a fact of life, and it also explains why the dough showed more signs of advanced fermentation when stored in the wine cooler (50F) than it did previously when stored in the fridge after the same fermentation time.

[Re: Fermentation timing factors 593](#)

Can you mix your dough at a higher speed? At a higher speed centrifugal force will pull the dough off of the hook providing better mixing action.

[Re: Does my dough look "off" after Kitchen Aid and folding? 594](#)

Dough is typically a bit more sticky and may tend to tear a bit more but otherwise manageable.

[Re: Does my dough look "off" after Kitchen Aid and folding? 595](#)

The yeast is for leavening and the L-cysteine is for making a dough that is easy to

mix and exhibits little or no dough memory/snap-back when opening the dough into a skin without any real fermentation time on the dough. If it were me, I'd have formulated that product using glutathione aka dead yeast instead of L-cysteine, that way it would not have shown up on the label, or at the very least it would have had to be labeled as containing both live and dead yeast cultures, either way it would sound a lot more consumer friendly.

Probably wouldn't hurt to have a few packets of this stuff on hand just in case you want to experiment with making a short time dough, like equal amounts of the Pizza Yeast and regular yeast in conjunction with a total fermentation time of 4 to 8-hours as opposed to 24 or more hours.

[Re: Fleischmann's 1/2s pizza crust yeast?596](#)

31 and you got feed back. :-D

[Re: Does my dough look "off" after Kitchen Aid and folding?597](#)

Regardless of how long the dough was mixed, it is still under mixed. Do you have a plain "J" aka "C" hook or do you have a reverse spiral dough arm for your mixer? Unless you have a reverse spiral dough arm you may never be able to mix a small size dough and achieve any significant level of gluten development. Remember, you should not go by a time recommendation, instead always mix just until the dough begins to take on a smooth appearance.

[Re: Does my dough look "off" after Kitchen Aid and folding?598](#)

I'd like to help you but I really need to know what you are presently doing so I can make some effective recommendations. Please provide your complete dough formula and dough management procedure (be sure to include all times, temperatures, dough weights and pizza sizes). In any deck oven the best you are going to get is about a 7 to 8-minute bake, and this might be stretching it a bit.

[Re: I need some help altering my dough recipe to cook at a higher temperature.599](#)

You should not be proofing the donuts on paper, this is why we always proof our donuts on a tight mesh 6mm X 6mm wire screen as this allows for air circulation to the bottom side of the donut. I also think you would be better served having more oil in the frying wok. The donuts DO look a lot better now! :chef:

[Re: on fat : oil, margarine, vegetable shortening, butter600](#)

When you say the dough was hard to open, in what way was it hard to open? From your pictures it looks as if it should have been pretty easy to open at 24-hours. You also mention that you mixed the dough until it came together as a ball but it appears that you did not mix it until the dough just began to take on a smooth appearance, this would explain a sticky dough off of the mixer and the roughness as well as tearing seen in the first dough ball picture. If you are experiencing an excessively soft and weak dough condition it is entirely possible that your starter is stronger than you might think it is so you would need to use less to compensate for this.

Also, regarding your dough formula, when showing the ingredient percentages you should be showing the total dough absorption percent in bakers percent. You are showing it in "true %" but not in bakers %. Bakers % for absorption = total weight of all water added to the dough divided by the total flour weight in the dough (do not include the flour in the starter) X 100.

[Re: Dough management question - tough dough starter601](#)

A lump or ball of dough will not cool down very well at all, especially if it is HOT. I suggest flattening the dough out as much as possible making it thinner and with a greater surface area, it will cool faster and more thoroughly thus preventing more damage to the dough due to over fermentation.

[Re: question about Doughmate artisan box size 602](#)

Go to Italy and/or Egypt and start a sourdough starter using spelt (the most commonly used grain in the region in "ancient" times), and hopefully whatever you get growing will be similar to what might have been fed to those who were building the pyramids, or painting pictures on walls, but keep in mind that environmentally, things have changed over the last 2,000-years or so it's still going to be a bit of a crap shoot if you end up with something original or not.

[Re: yeast 603](#)

We made them all the time, just use a HIGH COLOR CHEDDAR CHEESE POWDER and add it right on top of the flour just like any other dry ingredient, then mix the dough in the normal manner. I'm betting that you didn't add the necessary additional water to compensate for the dry cheese powder..right? I don't remember what the water correction was for the cheese powder but you can determine it for yourself very easily by placing a known weight in a small bowl and SLOWLY adding water while stirring JUST until a thick paste is formed, then divide the weight of water added by the weight of the cheese powder and multiply by 100. This will give you the percent additional water to add based on the weight of cheese powder you're adding. For the product that we were using 5 to 8% worked pretty well for us.

By the way, this is the same cheese powder that is used on Cheetos. When you look at it you will say "No Way!" the stuff is almost fluorescent, but trust me, nothing else will give you the color you're looking for. Flavor, like you said, it ain't nothin' to write home to Mama about.

[Re: Making bagel dough with 00 flour 604](#)

In that case I think this may be your best approach; Prepare a sponge (50% of the flour and 50% of the total dough absorption/water weight plus 1/3 of the total yeast). Use 70F/21C water, mix for 4-minutes (target temperature is 75 to 78F/23.8 to 25.5C) and set aside to ferment at room temperature for 4-hours.

Add fermented sponge to the mixing bowl along with the other ingredients (except for the oil), mix at low speed for 2-minutes and add the oil gradually, continue mixing at low speed for another minute then mix at medium speed for 5 to 8-minutes or just until the dough takes on a smooth appearance.

From this point process the dough as you normally do.

Note:

I do not recommend using semolina flour or any of the "additives" mentioned at this time.

If you want the dough to proof/rise faster in the pan increase the dough temperature, do not increase the yeast any more than what it already is. 5% CY is a LOT of yeast.

Your dough as you have presented is severely lacking in fermentation which is why I'm suggesting the use of a fermented sponge to provide additional flavor and dough conditioning.

If you need more crust color you will need to increase the sugar level (see my previous recommendation).

You are baking your pizzas at 500F, if you are trying to make a pizza similar to P.J.s

have you tried using 450F like P.J. s does?

[Re: Creating something new and standardised.](#) **605**

That's the reason why I like to ball immediately after mixing, place into box, wipe the top of the dough balls with oil and place them directly into the cooler/fridge. Once the dough has proofed like that it is hard to cool it down at a consistent rate so you end up with fermentation varied all over the board.

[Re: question about Doughmate artisan box size](#) **606**

Three things come to mind here;

- 1) Diameter of baking container (skillet/Dutch oven, not sure which you're using) as compared to the inside dimensions of the oven chamber.
- 2) Bottom heat only. Bread typically does not like to be baked with a lot of bottom heat (you just found that out) :)
- 3) Bad door seals allowing too much heat to escape from the oven.

Assuming you didn't use a shoe horn to get the pan in the oven we can set that one aside for now unless you have something to add?

Your IR thermometer should tell you if the door seals are sealing as they should, let's assume they are.

That leaves the bottom heat only explanation (#2). Here is a test for that theory, move one of the racks to a high position (hopefully you have more than one rack in your oven?) place some bricks/stones/ anything that will absorb a lot of heat and release and release it back into the oven. Preheat the oven (you will need to make sure the bricks, etc. are fully up to temperature) then place the bread in the oven and turn the temperature down to 400F. Allow the bread to bake (I'm guessing 20-minutes?) undisturbed before checking it. If you see any kind of improvement (no charred bottom and at least some top crust color) this would be an indication that you're on the right track. If not we'll need to rethink. When I used to make camp bread using my Dutch oven I used to put some hot coals on top of the lid to get the necessary top heat for crust color development.

[Re: New Oven Blues](#) **607**

Moneeb;

I see a number of issues here with what you are doing. The dough formula is out of balance as is the dough management procedure for a P.J. style of deep-dish pizza.

Here is your dough formula in bakers percent along with suggested changes:

Flour: 100%

C.Y.: 5% (reduce to 1%18-grams)

Water: 55.5% (adjust temperature to 60F/15.5C)

Oil: 5.5%

Salt: 1.38% (increase to 2%/36-grams)

Sugar: 0.5% (increase to 3%/54-grams)

Suggested changes to your dough management procedure:

Immediately after mixing cut into desired weight pieces, form into balls, lightly oil each dough ball and place into individual plastic bread type bags, pull the bag slightly snug to the dough ball and twist the open end into a pony tail, tuck the pony tail under the dough ball as you place it in the cooler to cold ferment for at least 24-hours. Remove from cooler and allow the temper AT (AT) room temperature until the internal dough ball temperature reaches 50F/10C, roll the bag down around the dough ball and invert the bag allowing the dough ball to fall onto a floured surface, flour both sides of the dough ball and shape to fit the pan,

place into a dark colored, deep-dish pan that has been well oiled, cover the pans and allow to final proof/tide until the dough has risen about 1/2-inch/12.5-mm, then place in the fridge for storage until needed. Note: The panned dough will not keep from one day to the next. You can incorporate any left over risen dough into fresh dough if the amount does not exceed 15% of the fresh dough weight, or you can make it into another product like bread sticks or garlic knots.

Question: What is a "convertible" conveyor belt oven? Do you mean an air impingement oven?

[Re: Creating something new and standardised](#) **608**

Peter;

Now's the time to give it a "whirl". Even if it ends up looking like the dog chewed your hair off nobody will even notice, that seems to be the new fashionable look today, and if anybody should comment, just tell them its the new "social distancing" look. :-D

[Re: Haircuts in an Age of Lockdowns and Self-isolation](#) **609**

12% protein should work OK for you. Cover = apples: Uncovered = bagels
When you make them be sure to cover a few to see for yourself.

I was once on the precipice of being charged with manslaughter during one of our bagel classes after I asked one of our students to take a full rack of just formed bagel dough to the retarder/cooler, little did I know that when he did so he also covered all of the racks of dough with rack bags, by the following morning the hole has all but disappeared and when they baked they actually rolled over! Being the instructor I had to retain my composure so we made it into a "learning lesson", not wanting to lose several hundred bagels I said, "Let's try something different to see what happens", I fired up one of our air impingement ovens (375F) and we baked a few of the "bagel bombs" just to see what would happen. You have heard me say many times that we can learn from our mistakes as well as our successes, well those bagels turned out ABSOLUTELY BEAUTIFUL, great shape (small hole more like a steamed bagel) but otherwise great! If there was a complaint or fault with the bagels it was with the color/appearance of the bagels after baking, they had a bright shine (more like that on a pretzel) and they looked almost like a plastic bagel. We found out later that this was the first successful baking of bagels in an air impingement oven. Why? Because prior to this everyone was following the correct dough management for making bagels. It's ironic that both bagels and pretzels are theorized to have been made accidentally when the baker's formed dough piece/pieces fell off of the oven peel and landed in the bucket of water used to swab out the oven. So another accident took the bagel to yet another level.

[Re: Making bagel dough with 00 flour](#) **610**

I've sported a full beard (for over 20-years now) and a flat top (something you don't see too often these days) since the 60's. Many barbers today don't even know how to cut a flat top so I'm getting ready to change over to a crew cut when my flat top gets too shaggy. When I do, that'll probably be the end of my visits to a barber shop.

[Re: Haircuts in an Age of Lockdowns and Self-isolation](#) **611**

To use powder in place of syrup use 80% as much powder as syrup. Like the name implies it's a "basic formula", sure, you can add some non-diastatic malt powder to replace the sugar in the dough formula if you want to, not a problem.

[Re: Making bagel dough with 00 flour](#) **612**

N.Y. style kettled bagels are typically made using a high protein content flour (13 to 14+%) which provides both the shape as well as the chewy eating characteristics. I've personally never made bagels using a "00" flour but there are many different types of "00" flour as well as the GM "00" type that you have. What is the protein content of your flour? That should tell a big part of the story.

Here is a basic bagel dough formula.

Flour: 100%

Salt: 2%

Sugar: 0.6%

Water: 53%

Yeast (CY) 0.75%

Mix: Mix in low speed for 2-minutes then in 2nd. speed if possible for about 10-minutes, if this is not possible mix for about 16-minutes in low speed. The dough is going to be VERY TOUGH.

Targer finished dough temperature is 76 to 78F.

Take the dough to the bench, remove from bowl and allow to rest for 5-minutes.

Then scale into 3-ounce pieces. After all of the dough is scaled begin shaping each piece into a rope about 6 to 7-inches long, wrap around your first three fingers to form a ring, then seal the two ends together (you can do this by rolling the formed bagel on the bench with the seam facing down. Place onto pans heavily dusted with corn meal, and place in the fridge for 24-hours (DO NOT, DO NOT COVER IN ANY WAY).

Remove the formed bagels from the fridge and allow to set AT room temperature for 20 to 30-minutes (DO NOT OVER PROOF).

Carefully place proofed bagels into boiling water to which 2.5% non-diastatic malt syrup has been added (2.5% based on the weight of the boiling water). The bagels will sink to the bottom of the water pot but should float in about 30-seconds. Allow bagels to boil for 30-seconds on each side then remove from the water using a screen or slotted spoon and place into a cold water bath for a few seconds, remove from the cold water and place onto an oiled parchment paper lined pan (a perforated pan is preferred, but lacking that you can bake on a solid oven deck or on a large pizza screen covered with the oiled parchment paper. Toppings can be applied at the time the bagels are about to be placed into the oven for baking. The bagels should be baked at 400F for about 20 to 25-minutes.

[Re: Making bagel dough with 00 flour](#) **613**

The only real way to determine maximum dough absorption is by conducting a series of test bakes with each bake identical with the exception of a progressively higher dough absorption for each dough. I recommend increasing the dough absorption in increments of 2% until you reach a level where you either cannot handle the dough anymore or the dough fails to perform at giving you the finished product characteristics you're looking for.

The "W" factor has little to do with it.

[Re: Flour and water](#) **614**

It really doesn't require much at all, what you are probably observing is the effect of pressure on the dough which inhibits its height in the container. A larger size container will not demonstrate this as well as a smaller size container (assuming the same amount of dough in both containers and all things equal).

[Re: Completely cover dough when proofing?](#) **615**

What it boils down to is that in our own homes we can pretty well do whatever we please, and if we get sick, well that's our problem but if you're a commercial food

establishment let's see? How many people could you potentially sicken, or perhaps worse? That's where the issue is at.

When I was a kid growing up on the farm we used to make potato salad all the time, we never refrigerated it, just laid a towel over the bowl on the table for the next meal, think about that..POTATO SALAD! Most every summer I would get what we called the "summer flu", it wasn't pleasant but I always managed to live through it. It wasn't until I took my first class in food pathogens and food safety that I found out that it wasn't a summer flu (whatever that is) that I had, it was a plain and simple case of food poisoning, most likely due to staphlococcus aureus (staphylococcal food poisoning). It wasn't a big deal and it never made the headlines but today, if that were to happen in any food establishment we would be reading about it in headlines, that's the type of publicity that a food establishment really doesn't want which is why they usually do their best to take the necessary precautions to prevent this from happening.

[Re: Completely cover dough when proofing?](#)**616**

Yes, that's why yeast raised donut doughs are only bulk fermented for 1-hour.

[Re: on fat : oil, margarine, vegetable shortening, butter](#)**617**

Have you tried putting it on later in the bake?

[Re: Too watery fresh mozz](#)**618**

We used to call them "pizza rolls". We make a variation of this at AJ's using just a piece of cheese and call them "cheese bricks". We got the idea from the Totino's Pizza Rolls back in the 60's.

[Re: Anyone ever tackle pull apart or rip apart pizza?](#)**619**

The enzymes and acids in the sourdough starter denature the proteins and while it is true that salt will strengthen the gluten forming proteins if they have been denatured there is nothing left to strengthen. True, all of the protein has not been denatured so you will get some strengthening, but probably not as much as you might be hoping for.

You might try adding 2 or 3% vital wheat gluten to see if that helps any.

[Re: Salt for a tougher dough?](#)**620**

This is one of those cases where dark is good and darker is even better!

Don't worry, you're good to go! :chef:

[Re: Did I just ruin my baking Steel?](#)**621**

Ascorbic acid is very quickly converted to dehydro-ascorbic acid which is an oxidant, much like ADA (azodicarbonamide, or potassium bromate) but much faster acting. How fast? It has fully reacted before the dough leaves the mixing bowl, so look at AA as an acid in this application, instead focus on Lactic Acid, Acetic Acid, Citric Acid, Fumaric Acid, and the like.

After mixing the dough, how much fermentation (at what temperature) do you give the dough balls before opening into skins?

Your friend is correct about both mixing (mix just until the dough begins to smooth out, and don't try to make cannon balls out of the dough when rounding)

[Re: The effect of acids on dough strength?](#)**622**

Rolls;

If you watch the dough being mixed in a food processor the blades do cut through the dough but at the same time the dough is being rolled around/moved, otherwise

the dough would eventually be pureed. Additionally, those gluten strands that we talk about are really quite small and bond back together again very rapidly. This is the reason why doughs that are made by high speed mixing processes tend to be a little tacky or some might say sticky immediately after mixing but literally within seconds take on a more normal feel.

[Re: Two Random Questions For The Dough Doctor](#)**623**

A man after my own heart! Use math!

3.9524 6-inch pizzas, you will have to decide who gets the one with less dough in the crust. :-D

[Re: A pizza question that's got everyone at work bamboozled](#)**624**

What it sounds like you're experiencing is what we call a "bucky" dough condition. While acids do indeed break down proteins, there is a point in the degradation of the protein where just before fully relaxing they tighten up (think of it like a muscle cramp) making the dough all but impossible to do anything with. At this point the only salvation for the dough is to put it back into the mixer and remix the dough which seems to help quite a bit.

Now, if by "tenacious" you mean the dough was pliable but exhibited a lot of memory (snap back) but didn't exhibit any major tearing when trying to open it, a condition like that would be more indicative of an under fermented dough. This could be due to a number of things but my first suspicion would be a poor performing sourdough starter. A good way to test for this would be to make another dough using the same starter but increase the amount of starter added to the dough by at least 25%. My experience has been that plastic starters (like sponges) do not acidify as well or as quickly as a liquid starter does. This is because the flour is more concentrated and it is the flour that tends to buffer the system from pH change as measured by TTA (titratable acidity). You'll have the same acids present just in less quantity and quantity is what it's all about.

As for hard water v/s soft water, we have discussed this topic many times. The calcium content in hard water acts to strengthen the gluten forming proteins in wheat flour, it also acts as a buffer to pH change. These changes are not dramatic but they are there. In commercial operations where we have stores or bakeries in different areas or municipalities with variances in hard and soft water we adjust for this by including 0.25% calcium sulfate in all of the dough formulas by doing this regardless of the hardness of the water being used, the dough reacts in the same manner as if all of the water was hard water.

[Re: The effect of acids on dough strength?](#)**625**

From a functional standpoint the addition of diastatic malt to a dough made with a malted flour is a moot issue, however if the flour you're using is not malted the addition of diastatic malt to the dough will help to improve the fermentation of the dough by converting some of the starch into sugar as a nutrient for the yeast to feed upon, it will also provide a significant contribution to the crust color of the baked product. The amount to add will vary with the strength (degree L/intner value) of the diastatic malt product. Addition of excessive diastatic malt can result in a gummy crumb texture.

Non-diastatic (non-enzyme active) malt is really just another type of sugar that can be added to the dough. It is unique from other sugars in that it can provide a very unique "malty" (think malted milk balls/candy) at higher levels or a more subdued flavor at lower levels.

[Re: LDMP](#)**626**

Yael;

Actually they have found that wood has certain anti-microbial properties while those scratches in the plastic are difficult to clean and constitute harborage for the bacteria.

[Re: Completely cover dough when proofing?627](#)

When making large quantities of dough, the same container is almost universally used for both mixing and fermentation, unless you're taking hours to mix your dough the crust that forms on the bowl will not be so hard so as to be impossible to incorporate back into the dough.

The VCM (vertical cutter mixer) doesn't chop the gluten strands into little pieces, it does a fine job of developing the gluten. Horizontal versions of the VCM are used in some commercial bread making applications where thousands of pounds of bread dough are produced every day. The only problem with the smaller (vertical VCMs) is that they have no provision for cooling the dough so as multiple doughs are mixed the bowl needs to be periodically cooler using ice water or the friction created during the mixing process will drive the dough temperatures through the roof. Also, since dough mixing times are very short in the VCM it is VERY EASY to over mix a dough. Considering that a normal mixing time for a bread type dough is about 70-seconds you can see how 10-seconds can make a big difference. Pizza doughs are mixed even less! The same applies to the food processor when it comes to mixing the dough but the mixing times will be different.

[Re: Two Random Questions For The Dough Doctor628](#)

It keeps as well as any regular flour BUT whole-wheat flour is a totally DIFFERENT matter with a room temperature shelf life of 2 to 3-weeks on the outside.

Refrigerated or frozen not a problem. The issue is with the germ/germ oil that's present, it is not very stable at all wanting to go rancid at the drop of a hat.

[Re: Semolina Flour Shelf Life629](#)

We have some good charts here that will serve to guide you in determining how much yeast to use when fermenting under specific temperature conditions.

[Re: Yeast question and ratios630](#)

Like I said, "If it doesn't kill us it just makes us stronger". ^^^

[Re: Completely cover dough when proofing?631](#)

Oops! I misread your post, thought you were wanting to freeze the starter. :-[There is no need to vacuum seal the frozen dough. It should be able to be frozen in a home freezer for up to 2-weeks without too much of an issue, after that you're on your own as viability becomes quite inconsistent.

To thaw the frozen dough, remove it from the freezer, unwrap and place into suitably sized container (lightly oiled), cover (but not air tight) and place in the fridge to thaw overnight, on the following day bring it from the fridge and allow to warm just until you can easily handle the dough then treat it just like you would fresh dough.

[Re: Freezing dough?632](#)

If it contains water it is part of the total dough absorption equation.

How are you using the simple syrup?

As for adding the sugar later in the mixing process, it sounds like you have a coarse granulation sugar that doesn't dissolve too readily. Can you get a finer/smaller particle size sugar?

You might also try adding half (5%) of the sugar right up front as this will not significantly interfere with gluten development and then add the second half about half way through the mixing process, then after mixing, allow the dough to rest for 10-minutes (this will give the late addition sugar a chance to further hydrate) and then mix/knead for an additional minute or so.

[Re: on fat : oil, margarine, vegetable shortening, butter](#)**633**

There was a M.A.S.H. (television series) episode where someone had stepped onto what was thought to be a land mine..Oops! Turned out to be the lid of a buried kimchi pot. :-D

[Re: Somewhere South.....](#)**634**

We used to have cloth (canvas) sleeves in all of our overhead intermediate bread proofers but alas, no more due to the sanitation issues. Ditto for bagel boards too. The "kicker" is that some of the required stuff is actually worse than the cloth or wood! For example, wood bagel boards and bench tops are actually more sanitary than the "plastic" they dictate that we use today. To the best of my knowledge there was never a problem with cloth or wood (wet/damp cloth is a different story) but there was always a "potential" for a problem, if we went through life thinking about what might potentially happen we would never get out of bed in the morning, but then a car might "potentially" crash into your house hitting your bedroom and you, safe and secure bed, sometimes ya just can't win! :-D

[Re: Completely cover dough when proofing?](#)**635**

Active cultures are commercially preserved by freezing but at much lower temperatures than you can do at home (-20 to -45F) but you can still freeze it as a means of preservation but because it is an active culture there is not real way of telling just how long it will remain viable. An interesting test would be to freeze it in an ice cube tray, individually package enough cubes to make a dough and then begin test baking at 30-day? intervals to see how well it holds up in your home freezer. Be sure to make and document (pictures) a control made with the sourdough before freezing.

[Re: Freezing dough?](#)**636**

If you want to do a Korean or Asian themed pizza try using sesame oil and put some sesame seeds on the rim of the crust before baking (brush the edge with 1-egg white whipped into 1-pint of water, this will be a binder to hold the sesame seeds in place on the crust). If you use a pan or disk put the seeds on the pan/disk so they get baked into the dough..delicious!

[Re: Somewhere South.....](#)**637**

The yeast was released for commercial testing (I cannot disclose much more than that). To see if there were any of what we fondly refer to as "hidden" issues which are brought to light only with long term testing. I had planned to meet with the manufacturer at Pizza Expo this year (the only meeting I had time for) but we all know how that turned out, so I'm, going to have to make a telephone call to see where they're at with the yeast. When I looked at it originally I encountered a couple of little idiosyncrasies that I had not planned on but we were able to overcome those pretty quickly so I think it holds a lot of promise.

[Re: novel yeast](#)**638**

We used it in combination with dried squid on pizza in preparation for the Asian Games in Seoul a number of years ago. We didn't have much of a selection in

cheese so we just used a mozzarella cheese which was available there at the time. When combined with fresh vegetables the dried squid came across a lot like a mild version of anchovy. When the kimchi was added up front it lost too much of its character but when we added it right at the end of the bake it was delicious! I've not made any Korean themed pizzas for a very long time, you've got me to thinking now that when the garden comes in I might run over to one of our excellent Korean food stores (Fort Riley is very close by and has several excellent Korean grocery stores (just like the one shown in the last episode) so kimchi is always easy for me to get.

Damn! If we didn't have this "stay home" order in place and if the restaurants were open we could go out for some Korean dinner, oh well, maybe another day. :'(

[Re: Somewhere South.....639](#)

Yael;

We did a study a number of years ago on kitchen sanitation using the homes of a randomly selected group of our own employees. We did swab tests in the kitchen as well as the main bathroom, what we found was very interesting to say the least! The most dangerous room in the average house (from a microbial stand point) was the KITCHEN! The #1 offender was the kitchen towel and the #2 offender was the counter top. Based on this we looked at the "chef's" towel, the one that our television chefs love to wear at their waist. We found that it was a literal petri-dish of bacteria (moist and warm). Based on this we stopped using them at AIB and we included it in our instruction materials as well as restaurant audits. I keep thinking of the old adage "That which doesn't kill us will just make us stronger". There must be something to it.

[Re: Completely cover dough when proofing?640](#)

She does seem to come across as pretty arrogant but so do a lot of other "chefs" so I just dismiss that. I did like the first show on dumplings, I'm planning to make some cherry soup this summer with dumplings so it was of more than a passing interest to me. The second show on pickles and sauerkraut was also interesting as I was raised on a German farm, need I say more? ;D

And I might add that I developed a special fondness for Korean Kimchi during my many trips to Korea, I like to refer to it as Korean sauerkraut. I still remember when flying into Kimpo International Airport and making the final approach and looking out the window and seeing all those kimchi pots on the roof tops, GOOD STUFF! :drool:

[Re: Somewhere South.....641](#)

The type or amount of yeast used has nothing to do with the dough yield. The amount of yeast used can be varied as a means of regulating the amount of fermentation the dough receives during a period of time under specific temperature conditions. For example an emergency dough that will be ready to make pizzas from in a matter of a couple to a few hours will contain significantly more yeast than a dough which will be fermented at room temperature for an extended period of time at room temperature. If the dough that is to be fermented for a long period of time at room temperature were made with the same yeast level as the emergency dough it would be extremely over fermented (excessively weak and have poor oven spring properties to name but a few of the over fermented characteristics). The three main types of yeast that are used are Compressed yeast (CY) aka fresh yeast/block yeast/wet yeast; Active dry yeast (ADY) aka dry yeast; and Instant dry yeast (IDY) aka instant yeast/bread machine yeast/quick rise yeast. Each of these yeast types are handled differently. CY can be crumbled and added

directly into the flour or it can be suspended in the dough water with no special handling precautions, that's the good news, the bad news is that it must be kept under refrigeration and it is perishable with a shelf life that can range from a week or so to a few weeks depending upon the age of the yeast and the storage conditions. ADY is essentially the same yeast as CY but it has been dried to a lower moisture content for storage stability, because of this there is more leavening power pound for pound in ADY than there is in CY, thus to achieve fermentation similar to that of CY the ADY must be used at a lower level (lesser amount). The substitution for using ADY to replace CY is to use 50% of the CY as ADY (use 1/2 as much ADY as CY). IDY is again essentially the same as CY but it has been made using a different drying process and it has been dried to a moisture content even lower than that of ADY making it the most concentrated of the three on a pound for pound basis. When replacing CY with IDY the substitution is to use only 38% as much IDY as CY to get equivalent fermentation.

Is there a difference in performance of finished crust flavor between the three different yeast types? No, they have been engineered to have essentially identical performance characteristics.

Why one over the other? Convenience and shelf life stability. CY can be added to the dough very easily without any special handling or addition methods BUT it is quite perishable and must be kept refrigerated for the duration of its somewhat limited shelf life. ADY has a rather long shelf life (6-months unopened) but may be shorter after opening, on the down side it must be pre-hydrated and activated in 100F water prior to addition to the dough. IDY has a very long shelf life (1 to 2-years unopened and 30-days or more after opening), it is also easy to use as it does not require pre-hydration and activation prior to addition to the dough, instead it is just added (dry) right on top of the flour. The one exception to this is when the dough will be mixed by hand, the IDY then needs to be pre-hydrated in 95 to 100F water BUT it does NOT require activation as the ADY does. The one cautionary note regarding IDY is that it should never be put directly into the cold dough water, to do so will damage the yeast and result in a soft dough condition with diminished or inconsistent fermentation properties.

A quick search through the archives here will turn up quite a bit of excellent discussion on these different types of yeast.

That's it in a nutshell.

[Re: Yeast question and ratios](#) **642**

I've been watching it since it first came on here (first episode here was last week/PBS).

[Re: Somewhere South.....](#) **643**

Let's do the math..

Your dough formula calls for 10% total fat in the form of butter or margarine, both of these will consist of 80% fat and 20% water. So, in 10% butter/margarine there is 80% fat. 80% of ten is 8, so if you want to replace 10% butter or margarine with shortening you would only need to use 8% shortening, the other 2% can be added to the dough formula as additional water.

One of the problems with adding an emulsifier to a yeast raised donut dough formula is that it can result in a very gummy eating characteristic if the donut is consumed when still VERY fresh (that's when yeast raised donuts are at their best). It can also result in a higher than desired level of fat absorption.

[Re: on fat : oil, margarine, vegetable shortening, butter](#) **644**

I make all of my thick crust and pan style pizzas (including Detroit style) in my

home oven as 450F using a middle rack position.

When baking in a deck oven if I encounter problems with the bottom of the pizza getting too dark I just place a pizza screen under the pan to address the problem, it's amazing what a small air gap will do :)

[Re: Lloyd Pans - Bottom Burning](#)**645**

I've seen a towel used quite successfully, a dry towel I might add. The dough did not dry out at all. This was when I was in the Philippines. There is sufficient humidity in the air there (85+% R.H.) that the dough couldn't dry out if it wanted to, the towel was placed over the dough to keep the flies off of it, they are absolutely attracted to the fermentation aroma. There are places in the U.S. where you might get away with it in the summer but not in the winter too, for this reason I've always recommended that if you are going to cover your fermentation container with a towel, make it a damp towel, the moisture from the towel will help to humidify the air between the top of the dough and the towel which will go a long ways in preventing drying of the dough while its fermenting plus it will also keep the flies off of the dough. Back in the 50's it was common at pizzerias to mix a dough and leave it in the mixing bowl to ferment, the bowl was almost always covered with a wet/damp towel to keep drafts off of the dough and to prevent it from drying out. You have to remember that most pizzerias back then didn't have air conditioning so in the summer those kitchens were awfully humid and you could get away with it back then but today with air conditioning in that same shop it ain't gonna work the same way, not to mention the chatter that you're going to get from your food safety inspector.

[Re: Completely cover dough when proofing?](#)**646**

No, you didn't miss it, you're tight though, that subject is pretty far from my area of expertise. Outside of smoking some beef, venison pork and salmon and sugar curing half of a hog from time to time I don't have a clue about how commercially cured meats are made.

[Re: Pepperoni](#)**647**

In bread production there is no difference in functionality between shortening and oil. There is no difference in finished moisture content of the bread either, between shortening and oil.

Fat is a tenderizer and as such it helps to provide the finished bread with a more tender eating crumb structure. Without any added fat, be it oil or shortening, the crumb will have a tough, more chewy characteristic (think of French bread) and as the amount of fat in the dough formula is increased the crumb structure will become progressively more tender eating, this is usually referred to as improved mastication properties when speaking about white pan breads where a tender eating crumb structure is a desirable characteristic. While at one time shortening used to be the most commonly used fat in white pan bread production, today oil in dome form is almost universally used due to its ability to be pumped and metered into the dough mixer(s) without the need to heat the fat or have heated delivery lines to the mixer. Just as in pizza dough production it is also common for the oil to be added to the dough after the dough has been mixed to some extent to reduce the possibility of the oil soaking into a portion of the flour thus rendering that portion of the flour incapable of producing gluten during the mixing process. What role does any fat (oil or shortening) play in white bread production? It helps to seal the cell structure for improved gas retention resulting in improved loaf volume characteristics, it also lubricates the dough which also contributes to improved loaf volume. It provides a method to regulate the mastication properties

of the finished bread. The ability of a fat to retain flavors helps to provide depth and dimension to the flavor of the finished bread while at the same time imparting a type of mouthfeel to the bread which is perceived by the consumer as "richness". Since fat also inhibits moisture migration and moisture absorption the bread is not perceived as being as dry when fat is included in the dough formulation (moisture is not drawn from the mouth as readily). This is why breads made without fat are commonly perceived as being "dry". Under certain circumstances the type and amount of fat can impact perceived crumb firmness, for example, oil is always a liquid, so if stored in a cool environment it will have essentially no impact upon the firmness of the finished loaf, on the other hand butter will recrystallize to nearly its pre-baked firmness as the loaf cools so if the loaf is stored at low temperatures (below 60F) it can result in a perceived firmer bread. This can be a critical quality aspect as many breads are frozen for distribution and then thawed at the point of sale, if the bread is not fully up to ambient store temperature when the consumer picks up the loaf they can perceive that the loaf is firmer and reject it for a softer loaf which is perceived as being fresher. The use of fat in the dough formulation can also impact the appearance of the finished loaf in that the baked crust will have a more attractive, lustrous hue to it (the color itself doesn't change but the way the crust reflects light does). Lastly the oil provides a source of enhanced lubrication for the slicer blades during the slicing and packaging operation.

Note: Butter is a standardized product so the properties of the butter can influence some of the above cited effects, for example many U.S. butters have a very narrow slip point so they go from rock hard to sloppy soft within a narrow temperature range while real Danish butter does not exhibit these characteristics, it is still soft and pliable at refrigerated temperatures while not turning soft and sloppy at elevated temperatures (this is where Danish pastry got its name from). Margarine, on the other hand, is a man made product which can be formulated for just about any application with any slip point desired which explains why it has a broad application in the U.S. baking industry. It can be formulated to mimic Danish butter, U.S. butter or it can be so soft as to allow it to be spread on fresh bread right out of the fridge while not melting into an oil at room temperature (you might know this as a "soft spread" margarine). A somewhat unique product to the bread making industry is what is referred to as a "liquid shortening", this is really nothing more than a plastic shortening to which oil has been incorporated and it usually also includes an anti-staling agent such as a blend of mono-diglycerides which work to help reduce the staling rate of the bread. Since these are usually added along with the fat it is a convenience factor to the baker to have these materials included into the liquid bread shortening.

One last thing, butter naturally has 18 to 20% water and table grade margarine, being formulated to replicate butter also has the same water content. In some applications this water has to be taken into account when calculating the total dough absorption, for the most part it isn't but at high fat levels (above 8%) many bakers will account for the water in the butter/margarine.

I probably missed a few points here but this should give you a pretty good idea of how these different fats function in a white bread system.

[Re: on fat : oil, margarine, vegetable shortening, butter](#)**648**

If you were using a commercially made frozen dough it most likely contained L-cysteine (almost universally used in commercial frozen dough) which always results in a soft and very extensible dough after thawing which would explain the need for a bowl. Even non-commercially made frozen dough will suffer much of this same fate as the static freezing (freezing at temperatures above -20F) will damage the yeast cells allowing for leakage of glutathione (very similar to L-cysteine) from

the cells upon thawing of the dough.

[Re: How can I keep my pizza round and 16"?649](#)

Now I understand what you are doing, I think that by twisting the open end of the bag into a pony tail and tucking it under the dough ball as you place it in the fridge will result in a more round dough ball after the 36-hour cold fermentation process, when we do it in in a pizzeria or when I do it at home getting a round shape has never been an issue as the pressure exerted by the bag forces the dough into a pretty round shape. After the CF period we just set the bagged dough balls on the side to temper AT room temperature (3-hours is a long time, with plastic bags about half of that time is more typical). The bag is then rolled down around the dough ball and the bag is inverted allowing the dough ball to fall onto a floured surface, then flour the entire dough ball and begin opening it into a skin by your preferred method.

[Re: How can I keep my pizza round and 16"?650](#)

OK, so now my old age is creeping up on me again and I'm confused. You said you were following the referenced dough formula and procedure so I opened it and that's where I got my information from, that's what you said you were following? Putting that aside, I presume you are bagging the dough BUT you are not pulling the bag slightly snug to the dough ball and twisting the open end into a pony tail and tucking it under the dough ball as you place it in the fridge, this, to a great extent, negates one of the great advantages of bagging the dough, that is the process which I'm reading into your reply leaves a significant dead airspace within the bag, thus insulating a good deal of the dough ball and not allowing for consistent cooling of the dough ball, not to mention that it provides a space for condensation to form (not a good thing). I would suggest incorporating the above procedure into your bagging process to see if it helps, it'll provide better dough ball cooling so at least it won't hurt. You should not be putting the bagged dough balls into any kind of container, a flat sheet pan is often used by pizzerias to place the bagged dough on in their coolers but dough boxes and lidded containers are counter productive in this case. A very popular reason for bagging the dough balls is the fact that they require no further attention once they are put into the fridge/cooler, there is no cross-stacking or down-stacking associated with bagged dough balls, for me this is a great convenience factor when making dough at home. Remember, experimenting is half of the fun, the other half is divided between learning from your experiments, eating your experiments, coming to the realization that you are rapidly making a whole new group of friends who just happen to love eating pizza as much as you do. :chef:

[Re: How can I keep my pizza round and 16"?651](#)

If you take a single mozzarella cheese and shred it to different particle sizes, from small cubes to a long shred you will see a progressively darker cheese color and the particle size diminishes (gets smaller), you will also see a significant change in the appearance of the top of the pizza as the cheese becomes more nondescript with the smaller particle size. For me, my preference is for a long, coarse shred as it gives better coverage and in my opinion, a better looking finished pizza.

[Re: How grate size affects melting652](#)

There are seven recognized proteins in wheat flour but only two of them are responsible for forming what we call "gluten", these two proteins are glutenin and gliadin.

L-Cysteine hydrochloride aka L-cysteine is indeed a dough reducing agent in that it

breaks the gluten bonds making for a softer, more extensible dough. Essentially all L-cysteine made today is synthesized as are many of the vitamins which are used in food production. If you cannot use L-cysteine check into using glutathione aka "dead yeast" it is 100% interchangeable with L-cysteine but is sourced directly from yeast by heating just enough to collapse the cell wall but not enough to denature the amino acid (glutathione). If yeast is acceptable glutathione will also be acceptable.

What application are you wanting to use the reducing agent in? For what purpose?

[Re: What exactly is the \$\text{iodine} \times \frac{1}{2}\$ protein content in flour? 653](#)

A 100-ml graduated cylinder would work I guess and you do know that there is a substitute for the balloon :-D but using one would probably require using a 250-ml graduated cylinder and a larger dough piece.

Or you could also fashion a simple gas trap.

[Re: IDY vs ADY vs bread machine yeast 654](#)

I've looked at the dough formula and procedure that you have referenced and I'd like to make a couple of comments. The dough formula calls for 63% dough absorption, do you know if this is the optimum dough absorption for the flour that you are using? Flour absorption changes and it is not uncommon for the absorption to change. My guess is that the absorption might be a little on the low side so you should consider incrementally increasing the dough absorption to see if that helps. Increasing the absorption makes for a softer, more pliable dough that will typically exhibit a reduced tendency to snap back aka "dough memory".

I also see that you are using metal fermentation containers and that you are NOT cross-stacking (leaving them uncovered until the internal dough ball temperature reaches 50F). This is a CRITICAL aspect to effective dough management as it allows for uniform cooling of the dough and also prevents or minimizes dough sweating which in nearly every case leads to a sticky/tacky dough at the time of opening. So, in my humble opinion these should be the first things to address, then if we need to we can dig deeper to resolve the problem. There are also some deviations in the dough formula which differ from what I normally use or recommend but we can address those later if we need to.

[Re: How can I keep my pizza round and 16"? 655](#)

Question #1: Yes you do. When substituting ADY for IDY you will need to use about 32% more ADY than IDY.

Question #2: IF, and that's a BIG "if" it is still as viable as it was when fresh/unopened, you would use the same amount.

An easy test to see if the yeast is still viable is to make a small dough in a cereal bowl (1/2 cup flour, pinch of yeast and a pinch of sugar) Put four tablespoons of warm water (100F) in the bowl, add the IDY and stir to suspend the IDY in the water, add the sugar immediately followed by the flour and stir, add more water as needed to make a dough, using your finger, oil the inside of a shot glass, then remove a piece of the dough large enough to fill half of the glass, cover with a damp piece of paper towel and check it for growth in 30-minutes. This will tell you if the yeast is still viable or not.

Another easy test is to make a slurry of 50 ml 100F water, 1-tablespoon flour and a pinch of sugar, stir this all together and pour into a test tube (I bet you have a case of them just waiting to be used for this), and then fit a balloon over the end of the test tube, place the tube into a glass or cup about 1/2 filled with 100F water. Check the back in about an hour to see if the balloon is beginning to inflate.

[Re: IDY vs ADY vs bread machine yeast 656](#)

If you go to my web site <www.doughdoctor.com> and look under "Media" you will have access to my videos. In the last of the dough making videos we show the dough balls being opened both by using a dough sheeter to pre-open the dough and also opening it entirely by hand (similar to the first video you've referenced as wanting to learn from).

[Re: Bench flour](#)**657**

Perfect! :)

[Re: Poolish amount](#)**658**

Rohfan;

Unless it has been upgraded to a reverse spiral dough arm (not sure if it can be) it will most likely have a very basic dough hook which you will eventually come to hate as the dough keeps riding up on the hook and doesn't get properly mixed. This tends to be more problematic with dough sizes anything less than full bowl capacity.

You will want to experiment with your mixer to see if you can mix smaller size doughs using the flat beater for a portion of the dough mixing time and then changing over to the hook and mixing at a higher speed to keep the dough from climbing up the hook. If you plan to make some of the higher absorption doughs this may not pose as great of a problem as the dough is easier to mix at a higher speed allowing centrifugal force to pull the dough off of the hook for improved mixing action. I know a number of members here have a similar problem with their K5-A so maybe they will be able to share with you what they have found to work at resolving this irksome trait of the old "J"/"C" hook design.

[Re: Newbie--Caputo's Tipo 00 dough recipe](#)**659**

Most of the time the set temperature for a poolish is between 75 and 80F, it is suggested that you that the water temperature used in making the poolish be about 2F less than the targeted set temperature. I never recommend "room temperature" as there is no definition as to what it might be. For some it might mean 70F while for other it might mean 60F or as I once found out in Hermosillo, Mexico it meant over 100F/37.7C! :o

[Re: Poolish amount](#)**660**

Your best bet will be to allow the dough balls to rest, undisturbed at room temperature until they have softened sufficiently to be opened into skins without tearing. If you want to make pan pizzas using the dough just grease a dark colored, deep-dish pan with Crisco (Butter Flavored Crisco is my favorite), but margarine or lard works well too. Flatten the dough ball into a puck shape and place into the pan, drape with a piece of plastic and allow to rest for 30-minutes, then using your hands, press and stretch the dough to fit the pan, don't worry if it fights you or pulls back, just cover it back up and allow to ferment for another 30 to 45-minutes, finish shaping the dough to the pan, it should stay put this time. Cover the panned dough with the plastic again and allow to final proof for 30-minutes, you're then ready to dress and bake.

[Re: Dough tears when balling? Can you over ball?](#)**661**

While that dough management procedure isn't designed for use with a poolish, it can be done. Use 1/3 of the flour, 1/2 of the water and all of the yeast in the poolish. Set temperature for the poolish should be 75 to 78F/23.9 to 25.5C, allow the poolish to ferment for 6-hours before incorporating it into the remainder of the

dough ingredients.

[Re: Poolish amount](#)**662**

First off, the "window pane" test for gluten development is used for determining the proper mix for a bread dough not a pizza dough. Pizza doughs are correctly mixed when the dough JUST takes on a smooth appearance. You do not want to mix the dough more than this. Allowing the dough to ferment for an hour before balling is just asking for the dough to tear during balling, especially with a strong flour like All Trumps. My suggestion would be to just scale and ball immediately after mixing, and then manage the dough as you wish from there.

[Re: Dough tears when balling? Can you over ball?](#)**663**

I would really need to know more about the dough to answer your question.

How long after the flour was removed from the freezer did you mix the dough?

What kind of flour are we talking about?

Protein content?

Dough absorption?

How big of a dough are we talking about?

How was it mixed, by hand or machine? If by machine for how long?

How was the dough managed?

I've got an idea but I want to narrow the field before casting my vote.

[Re: sticky dough?](#)**664**

Yes.

[Re: Help please](#)**665**

Do not use more than 24-hours CF for a T&B pizza. Adjust the dough formula by increasing the yeast level by 20% and reducing the dough absorption by at least 2% maybe more, depending upon what your present dough absorption is. Generally something in the 58 to not more than 60% range seems to work well, but again it will depend upon the flour you're using. Immediately after opening the skin place it on a silicone baking sheet and then onto a cardboard circle. Refrigerate for at least 1-hour, then dress and back into the fridge for another hour, then stretch wrap and refrigerate until ready to use. Bake directly from the fridge at 425F.

[Re: Take and bake dough suggestions?](#)**666**

Yep, your problem is that you are not fermenting a sufficient amount of the flour. Kyrol flour tends to require quite a bit of fermentation to properly condition the gluten. After making the dough, scale and ball it and cold ferment the dough balls for 48-hours. After the cold fermentation period remove the dough from the fridge and allow it to temper AT room temperature until the internal dough ball temperature reaches 60F, then begin opening the dough balls into skins. Let us know if this makes things a bit easier.

[Re: Help please](#)**667**

For the home pizza maker the term "cross-stacked" as indicated in my previous response, means left open/uncovered/unlidded. After the appropriate cross-stack period the dough box is lidded or covered in some manner so as to prevent drying of the dough during the fermentation period.

[Re: question about Doughmate artisan box size](#)**668**

Let's look at an order of progression, first adjust the dough absorption to a level that works with your mixing method and dough management procedure, then

based on that dough absorption begin a series of tests with progressively higher or lower absorptions to achieve the desired finished crust characteristics. All flours are not created equal, some will carry more water than others. You cannot arbitrarily plug in a high absorption, like 75% and expect that all flours will produce a dough with acceptable dough handling properties or the finished crust characteristics one is looking for. You have to find out what is correct for YOUR specific flour. When dealing with an unknown flour you always want to first get a working dough formula and procedure, then once you have that you can begin adjusting the formula and/or procedure to move it closer to giving you the characteristics you're looking for.

[Re: Dealing with poor flour](#)**669**

Sure! Just reduce the dough absorption to 60%. This is a pretty good place to bench mark just about any pizza dough formula from. Unless you have a really "off the wall" flour it will almost always give you a usable dough, you can then decide if you want to stay with 60% or adjust the amount up or down for better overall dough performance and/or finished product quality.

[Re: Dealing with poor flour](#)**670**

You'll have to excuse me but I'm a bit confused.

What ingredients were in the poolish? How much of the total flour was in the poolish? What was the temperature of the poolish?

I don't think enough of the flour is being fermented but answers to the above will tell.

[Re: Help please](#)**671**

Also remember that the Doughmate boxes will need to be cross-stacked (left open) until the internal dough ball temperature reaches 50F after which it can be covered/lidded. All of the other methods mentioned do NOT require this additional step in your dough management procedure which is something to consider if you will be making your dough after the sun goes down. I use the plastic bread bag method almost exclusively anymore, just bag it, put it in the fridge and forget it! :)

[Re: question about Doughmate artisan box size](#)**672**

Welcome!

There are many of us here who can help you with your endeavors. To help get you up to speed on all things pizza, there is also another web site that you will want to explore too <www.pmq.com> . There are also magazines dedicated specifically to pizza which are available through on-line subscriptions: Pizza Marketing Quarterly Magazine/www.pmq.com; and Pizza Today Magazine/www.pizzatoday.com

There are also quite a few good books on pizza production that are available from most on-line sources.

In the mean time, what is your concept for a store/pizzeria?

[Re: An engineer, wanting to start a pizza business.](#)**673**

HansB;

You did that just as a very competent well trained baker would do it, well versed in what we refer to as "bakers math". You think like I do. Do you have a background in the baking industry?

[Re: Help Scaling Tony G Sicilian Dough](#)**674**

There is bread and there is "bread", can you be more specific as to the type of bread that you are making?

[Re: Substituting Caputo 00 for KABF675](#)

It looks like you are definitely getting a more open crumb structure. You might make another increase in the yeast level and you might also consider putting some moisture into the oven, maybe placing a pan of water in the oven before the pizza will increase the moisture content of the air within the oven to give you better oven spring. Electric ovens bake with a very dry heat as there are no products of combustion in the baking chamber as there are with wood fired ovens (water/moisture is one of those products of combustion).

[Re: Bulk Fermenting vs. Individual Balls676](#)

People need bread so they're thinking of making their own, what kind of flour do you buy to make bread? Bread flour! If there were a shortage of bagels they'd all be buying "bagel" flour..whatever that is? During times of shortage I've always accepted the challenge to use whatever type of flour I could get my hands on, when traveling internationally back in the 80's we couldn't always find "pizza" flour or even "bread" flour but there was always some type of wheat flour available.

Sometimes it was even a composite flour consisting of 70% wheat flour and 30% fine ground domestic grains and legumes. In all cases we were able to make pizza from the flour, maybe not a New York style or a Neapolitan style, but it was a decent pizza and people liked it. The truth to the matter is that bread, pizza, bagels, pretzels, soft rolls and hard rolls can all be made from the same flour without any difficulty at all. The same goes for pizza in that it can be made from just about any kind of flour, yes you will need to make some adjustments in the way you make it but that's what learning about pizza is all about. What do you think the old pizza makers of 200-years ago in Italy did for flour? They used what they got and they learned, by trial and error, how to use it, and from the looks of the present day pizza industry they did a mighty fine job of overcoming their flour issues and got to the business of making pizzas. The same is true today, snag a bag of the "different" flour and experiment with it to broaden your learning curve, but what about the mistakes? Trust me, there will always be someone waiting just outside of the kitchen all to eager to help you make those mistake pizzas go away never to be seen again.

I relinquish the soap box. :-D

[Re: yeast and flour supply chain?677](#)

I did that too, I worked at AIB during the day (6:30 a.m. to 6:00 p.m. including travel time) dinner with the family and off to the store at 7:00 p.m. Worked at the store until 12:00 a.m. and back home to repeat on the following day. I did this for nearly 2-years until I got my staff and got them all trained. It's a tough grind to be sure! More importantly, I was A LOT younger then too.

[Re: Delay opening?678](#)

Also, remember that we go to all the trouble of preheating the oven and the stone/steel and then we open the oven to peel the pizza in, depending upon how proficient one is at peeling a pizza into the oven can have a huge impact upon how much heat is lost from the oven during the process. This is especially so with today's "200" Energy Star rated ovens.

[Re: Consistent white brim679](#)

Wotavidone has answered the question for me, spot-on! Thank you! ^^^
While approximately 10% protein content is a bit on the low side it is entirely doable, especially when mixing the dough by hand.

While there are many different ways to mix a dough by hand here is the way that I do it.

Put water in mixing bowl (70F) 60% of the flour weight.

Add the salt and sugar to the water (no need to stir).

Put the yeast in 5% of the flour weight of 100F water, stir to suspend the yeast. IF CY or IDY you can now add the yeast suspension directly to the water in the bowl, if it is ADY allow the yeast to activate for 10-minutes before adding it to the water. Immediately add the flour and begin to stir the dough with a wooden spoon, after a minute, or so, add the oil and continue mixing until the dough becomes too stiff to mix with the spoon, now begin mixing by hand until you have a homogeneous dough.

Turn the dough out of the bowl using a plastic bowl scraper to get it all out, lightly oil the bowl and the dough, knead the dough for a few minutes (3-minutes), form the dough into a ball and place back into the oiled bowl, cover (drape) with a piece of plastic and allow to ferment for about 2-hours.

Turn the dough out of the bowl again and knead it until it just takes on a smooth appearance, oil the bowl, form the dough into a ball again and place back into the bowl.

Cover the bowl with a piece of stretch wrap but do not seal it tightly, place in the fridge to cold ferment for about 24-hours (48-hours max.).

After the CF period bring the dough out of the fridge and allow it to warm to 60F internal ball temperature (about 90-minutes), turn the dough out of the bowl onto a floured surface, flour both sides of the dough ball and open into a skin by your preferred method.

[Re: Newbie--Caputo's Tipo 00 dough recipe](#)**680**

There should also be a nutritional panel too, what does it say?

[Re: Newbie--Caputo's Tipo 00 dough recipe](#)**681**

About a week or two out from opening begin making pizzas and send them out to local charities, police station, fire station, etc. This will give your crew a chance to practice and serve to advertise your presence. When opening, I would advise you not to do a grand opening, instead do a soft/quiet opening, if you have done your pre-opening work you will have customers coming in to check you out. This will allow you to work out any serving issues that might crop up (they always do) while allowing your staff to ramp up their skills gradually. In these trying times I don't think you'll get "hammered" as is usual for a new opening restaurant but you never know. Once your staff is comfortable and you feel ready for it, then is the time to consider a grand opening. Many of the restaurants that I've worked with never had to do a grand opening, once the word got out that they were open they were too busy for a grand opening! :).

Best of luck!

Please keep us posted.

[Re: Delay opening?](#)**682**

We have discussed cold fermenting dough balls in bags a number of times here so I'll just summarize. When cold fermenting the dough balls in bags DO NOT use ZipLock bags, instead use bread type bags. Lightly oil the dough ball(s) and drop into individual bags, twist the open end of the bag into a pony tail and tuck the pony tail under the dough ball as you place it in the fridge (DO NOT SECURE THE OPEN END IN ANY OTHER WAY), after the CF period remove from fridge and allow to temper AT (NOT TO, AT) room temperature until the internal dough ball temperature reaches 55 to 60F, then roll the bag down around the dough ball and

invert it over a floured surface or bowl of flour, the dough ball will invert the bag as it falls free. Flour both sides of the dough ball and open into a skin by your preferred method. Save the bags and store in a small covered bowl in the fridge for the next time you make pizzas.

Note: When placing the dough ball into the bag try to pull the bag snug, but NOT tight to the dough ball. If you search back through some of the threads on the topic I think you will find some good pics of bagged dough balls.

[Re: Thank you Tom the dough doctor](#)**683**

Yes to both of your questions. What can you tell us about the AP flour you have on hand? Can you sens a picture of the ingredient panel? The reason I ask is because all AP flours are not created equal, some are more like a bread flour while others are more like a pastry flour.

[Re: Newbie--Caputo's Tipo 00 dough recipe](#)**684**

I'll be brief. Delay the opening and DON'T quit the day job!!! ^^^

[Re: Delay opening?](#)**685**

Before you make the next bake try adding 2% sugar to the dough formula (flour weight X 2 (press the "%" key) and read the sugar weight in the display window.

Note: Ingredient weight will be in the same weight units (pounds, ounces, grams, etc.) that the flour weight was shown in.

Rather than baking the pizzas in a lower rack position you might also try raising the rack to a higher position (closer to the heat) as this should also help in getting better crust color.

Now, with all of that said, I might suggest one other thing, rather then starting with a "00" flour, set it aside for now and see if you can get a bag of regular bread type flour, use this flour to perfect your skills, dough formulation and dough management procedure, once you're enjoying some good pizzas that's the time to introduce the "00" flour and begin perfecting the dough formula and procedure with that flour.

[Re: Newbie--Caputo's Tipo 00 dough recipe](#)**686**

What shelf position are you baking on? If you are not baking on the highest shelf position try moving your pizzas to a higher position in the oven.

[Re: Consistent white brim](#)**687**

Yes one can. Find out how much protein your existing flour has and subtract this from the percent protein you want the flour to have, divide this number by 0.6 and that is the percent VWG you will need to add to bring your existing flour up to the desired protein level. Remember that you will need to increase dough absorption by 1.8% for each 1% VWG you add. Make sure to blend the VWG into the flour to prevent pilling of the VWG.

[Re: Modifying recipe to use Bread Flour Instead of KASL-Flour shortage due to Covid](#)**688**

I can imagine a scale that would require you to enter the temperature of the water and then a microprocessor would calculate the density and show the water as a volumetric measure in ml based on the weight of the water.

I think I'll just stay with my multi mode scale as I work mostly in metrics anyhow.

[Re: All in one scale? \(Precise and large capacity\)](#)**689**

I'm staying with my yeast guess.

[Re: Hilarious Result, But Delicious](#)**690**

Your best bet by far will be to fully bake the pizzas but to bake them to your minimum standard of being "done", to allow to cool, slice into desired size pieces, individually wrap each piece in cling wrap and freeze. I do not recommend trying to recon (reheat) the pizza directly from the freezer, instead either place it in the fridge to thaw or thaw at room temperature (you will need to work out the time needed to thaw as it will vary with the pizza). Place into a 350F oven to reheat. The time again, will need to be determined.

[Re: Pizza Hut Pan Pizza](#)**691**

Ml. on a scale? That's a first! :-D

[Re: All in one scale? \(Precise and large capacity\)](#)**692**

Dan;

You certainly came to the right place! Take a look at the posts on New York style pizzas and you'll find yourself chin deep in "high gluten" flour. :-D

[Re: Pizza dough](#)**693**

Try my New York dough formula but reduce the dough absorption to 56%, CF for 48-hours, allow the dough balls to temper to 50F internal temperature, open dough balls using a rolling pin or pastry pin to about 3/16-inch thickness, dock the dough well using a dough docker, fit the skin into a lightly oiled, bright colored (not seasoned) cutter pan, dress and bake at 500F. Bench mark from there and lets see how close that gets you.

[Re: Looking for a specific pizza dough recipe](#)**694**

As you didn't mention anything about the dough feeling different we'll "assume" that it felt pretty normal to you, so I'm guessing you might have made an error in scaling the yeast or possibly scaled it right but maybe used IDY instead of ADY which when used at the same levels would create a slight increase in overall yeast level. Just not enough information to make a better SWAG. In any case it's good to hear that you enjoyed the pizza regardless of what it looked like, like I always say "even our mistakes can taste pretty good".

[Re: Hilarious Result, But Delicious](#)**695**

Dasnyde4;

The only time you might really want to use a "high gluten" flour (14+% protein content) is when making a more authentic New York style pizza. The dough formula and procedure performs very well using just about any decent bread type flour, with the only real difference being that the finished crust will not be as chewy as it would be if made using a flour like All Trumps. It will still be chewy, just not as chewy. This might even prove to be a good thing for you as some prefer a pizza that isn't quite as chewy as a traditional New York style pizza.

Welcome to the forum and let us know if you have any questions or problems along the way.

[Re: Modifying recipe to use Bread Flour Instead of KASL-Flour shortage due to Covid](#)**696**

I occasionally run into the same problem, when I do I just place the pan on a pizza screen and bake it that way.

[Re: Steel Pans](#)**697**

And the baking temperature was?

[Re: First Delivery for our NY Style Slice shop concept](#)**698**

A number of years ago we did a study on similarity of flour by type from different manufacturers, we found that there was a very high level of similarity between bread, and H&R type flours. The so called "high gluten" flours were somewhat variable with some having a protein content as low as 12% while others were in the 13 to 14+% range. With AP type flours we found even greater variances as some AP flours were made from soft wheat varieties and others were made from hard what varieties with protein content all over the board from a low of 9% to a high of nearly 12%, and remember that there is a significant difference in the gluten characteristics between flours made using hard and soft wheat. Based on this study we developed the recommendation to be very cautious when changing brands of AP flour.

[Re: Starter suddenly stiffened](#)**699**

I love my KD-8000! We use it for when making jerky and preserves and anything else where we need to weigh something in the kitchen. Two scales are the way to go but if you don't have the accuracy range you want from a KD-8000 just weigh, put into water and stir, then divide. For example, if you want 1-gram of yeast, weigh two grams into two small glasses of 100F water, stir to suspend the yeast and portion out one of the glasses. What you will have in the glass will be close enough to 1-gram for making pizza dough. Be sure to include the water in the suspension as part of the dough water and you're good to go.

[Re: All in one scale? \(Precise and large capacity\)](#)**700**

In countries where noodle production is one of the major products made from imported wheat or flour and bread or pastry production is secondary I've seen a number of cases where the lower protein HRW (HRW #!) is blended with the higher protein durum wheat/flour to provide a higher protein flour option. Many international millers don't have any baking background so they have little or no concept of the ramifications this can have for the end user. Like I said, it just an educated guess based on the information provided. The relatively high ash content shown on the flour specification also shows that the flour is what we refer to as a high extraction rate flour (typical U.S. white flour runs at about 0.6% ash while whole wheat flour comes in at 1.0 to about 1.25%).

[Re: mixing and handling unmalted flour](#)**701**

Are you sure you want to leave the dough balls come all the way up to room temperature after the CF period? The dough can be problematic at room temperature in some cases, this is why pizzerias use 50F (internal ball temperature) and many home pizza makers use 60 to 65F (internal ball temperature) for the target temperature before opening the dough balls into skins. Poplar is probably one of the most common woods used for dough boxes and bagel boards because of its dense grain which doesn't tend to splinter like some of the hardwoods do. In the cracker industry, we used to use wood dough troughs for fermenting the cracker doughs (18 to 24-hours) and when the wood troughs were no longer permitted we found that there was a change in the flavor of the finished crackers. It was found that the wood would become inoculated with a strain of lacto bacillus which in turn migrated into the dough during the fermentation period resulting in a specific flavor development which could not be achieved in the mandated steel fermentation troughs. The specific strain of LB was identified and added as a supplement to the dough at the time of mixing thus restoring the

original flavor to the crackers. Keep in mind though that this is all based on using well used wood dough troughs (boxes in your case) and the dough was in the box for 18 to 24-hours. Cracker doughs are around 40% absorption so there was never much of a problem with the dough becoming one with the wood. Note that these wood dough troughs were never washed, they were just scraped clean for the next use. Cold fermenting the dough for 24 to 48-hours, or more in a plastic box and then transferring it to a wood box to temper prior to opening would serve no useful purpose.

[Re: Is there a benefit to using wood boxes for proofing?702](#)

It should work just fine, I've used the G.M. Sperry organic flour many times with my dough formula and dough management procedure with the added (optional) 2% sugar.

[Re: Giusto's Ultimate Performer for NY Style703](#)

It would if you took a break between suspending the yeast in the salt water and adding the flour, otherwise it would not cause any problem, on the other hand if the yeast amount was the same and you went from 2% to 3% salt (a 50% difference) that might explain the difference. What I suggest you do is to make the dough again but use only 2% salt, if you get better fermentation you'll have your answer, let me know what you find.

[Re: Forkish Saturday dough, too much salt?704](#)

Phil:

Welcome to the site! Hopefully we can help you make your dream a reality. Your ideas are sound, and buying "local" can be a significant benefit, try to incorporate that theme into your advertising. One word of caution though, while N.Y. pizzas are great, they may not be perceived that way by once you get away from the east coast. A case in point, I worked with a young man here in Manhattan, Kansas about 12-years ago in opening a N.Y. pizzeria. Got the pizza nailed down tight, sauce and toppings too, even the store decor...pizza was judged just ho-hum. The problem was that people in this area want and really like a crispy crust regardless of the type of pizza it is. We made changes to the pizza so we now have a VERY CRISPY crust but retained all of the physical appearance characteristics of the N.Y. pizza. Truth is, we now have a New Haven style pizza, but the customers love it, so much so that the owner, Adam Peyton, now has three stores and has been named "best pizza" numerous times, in our local market area AJ's Pizzeria is without doubt the preferred pizzeria. (AJ's New York Pizzeria, Manhattan, Kansas). Point is, know your market and give your customers what they want and you'll have a leg up over the saddle on your way to success.

[Re: Introduction - Pizza Truck Pipe Dream705](#)

Now I'm unconfused. ;D but I still have some questions as to exactly what you are wanting to do.

So we want to room temperature ferment our dough in dough boxes measuring approximately 18 X 24-inches, right? I saw your reference to a heat lamp but the refrigerator part leads me to believe this assumption might be wrong. Maybe you just want to use the refrigerator as an insulated box? I guess the questions I'm asking now is "what temperature do you want to ferment your dough at, and how many dough boxes are we talking about?

[Re: Wide enough fridge706](#)

Why do you want to proof the dough in your dough boxes? After CF just place at

room temperature and allow the dough balls to warm to 50 to 60F internal temperature before opening into skins.

Pan pizzas are proofed after the dough is fitted into the pan before dressing and baking.

Is there a possibility that you mean "fermentation" rather than proofing?
Please unconfuse me.

[Re: Wide enough fridge](#)707

The thing about SD starters is that it's a crap-shoot as to what you get. You really don't know what you're culturing/growing until you go to use it. Once you find something that you like treat it like you would important computer data, back it up! Start a second one using the first one to inoculate the back-up thus ensuring you'll have the same micro-flora. Then if you lose one you will still have another to work with and to propagate another/more from without losing the flavor or performance of the master S.D. starter.

[Re: Help - looks like dough is being eaten from the inside out](#)708

Use less potato.

[Re: mixing and handling unmalted flour](#)709

From a practical point in home use application the rate of deterioration between ADY and IDY is about the same.

[Re: Yeast storage and longevity](#)710

No, just the flour and the water for the autolyze. Add the potato into the dough not the autolyze.

[Re: mixing and handling unmalted flour](#)711

Easiest question to answer for the day: No.

Based on that I would move insufficient dough absorption to the bottom of my list of things to look at. I have never had any problem making bread or pizza doughs with just 20% added rye flour, it's not until you get up into amounts over 35% that things begin to get interesting with the dough unless additional VWG is added to help carry the rye flour. I think your approach is a good one to look at just the flour alone and then look at the starter and the added grains.

[Re: Help - looks like dough is being eaten from the inside out](#)712

RI;

I might add that with this type of dough it's important to suspend the yeast in the water and then add the salt and sugar, give it a quick stir and add the flour, then add the butter. The best way to add the butter is to cut it into pieces or shave it onto a piece of paper and then allow it to warm to room temperature, it is then added right on top of the flour just before you begin mixing.

[Re: Cracker style dough](#)713

No, just make the autolyze and add it to the bowl then the remainder of the ingredients (no more flour or water) and mix, then proceed as suggested or as you wish to.

[Re: mixing and handling unmalted flour](#)714

In a word, yes.

[Re: organic vs. non-organic flour?](#)715

From your description I am wondering if the flour might not be made from a specially milled hard red spring wheat which has a larger particle size (slower to hydrate resulting in a sticky dough). This would not be a durum semolina but more like a spring wheat semolina flour. We do the same thing here in the U.S. using hard red winter wheat varieties where the flour is designed specifically for making pasta.

Here is something to try, make an autolyze of the flour and 70% of the flour weight as water. Allow this to set for 1-hour, then add the remaining ingredients and see if you get a better dough. The absorption might not be correct but it should be better than what you have been getting and not as sticky either. If the flour is made from all spring wheat the dough should open pretty well after 24 to 48-hours cold fermentation but if the flour is made from a blend of both spring wheat and durum wheat you may find the dough to be too elastic for making donuts.

For your process, mix, (targeted finished dough temperature is 80 to 85F/26.6 to 29.4C), then bulk ferment for 1-hour, divide into 2 or 3Kg. pieces and form into loaves, cover the loaves and allow to ferment for 1.25-hours, then begin rolling the dough out to about 8mm in thickness, cut the donuts from the sheeted dough.

Place cut donuts on a frying screen or flour dusted cloth on a sheet pan or proofing board and allow to proof for about 45-minutes, fry approximately 1-minute on each side at 365F/185C.

Don't worry about the flour not being malted as your donut formula already has plenty of sugar in it.

[Re: mixing and handling unmalted flour](#) 716

There is a commercial method of scaling and balling that I show in one of my videos on my web site at <www.doughdoctor.com> very fast with one person balling approximately 85-pounds of dough in under 20-minutes (12-ounce scaling weight).

[Re: Balling](#) 717

We do begin to see some changes in the "brew" (which is what you are describing) after about 36-hours in the fridge but these changes are hard to see in pizza crust production (bread making is a TOTALLY different story) so you should be good doing as proposed, but since we are not propagating yeast we are only diluting the existing population of cells, with time you will find that you will need to add ever increasing amounts of the brew to maintain equivalent gassing/fermentation power.

[Re: Yeast](#) 718

Flour: 100% 500-grams

Salt: 1.75% 8.75-g.

Sugar: 2% (optional) 10-g.

Yeast: CY 1% 5-g.

Butter: 6% 30-g.

Water: 45% 225-g.

Total: 778.75-g

Bowl and fermentation loss: 75-g.

Yield: 703.75-g.

Use the trim dough to make a few bread sticks for appetizers. or just cut into strips about 1/2-inch wide and desired length to make a dipping bread stick.

[Re: Cracker style dough](#) 719

I use equal parts of regular white flour, FINE corn meal, and semolina flour. If you ask 50 different people what works best for them you'll probably get close to 50 different answers.

[Re: Bench flour](#)720

That's an impossible question to answer as I don't know how much damage the CY has sustained as a result of being frozen (CY does not tolerate freezing all that well). The best advice I can offer is to use it at 2.5 times your IDY level and see how it performs. If it appears slow you can increase the amount of CY but be aware that the freezing process will damage the yeast cells resulting in the release of glutathione into the dough making softer and more extensible than normal. To some extent this can be addressed by reducing the total dough absorption a couple percent. If you see any of this I wouldn't advise trying for any long fermentation times (limit CF to not more than 24-hours) as the softening will continue during the CF time.

By the way, unopened IDY can be frozen for up to 2-years with just a 25% loss of activity.

[Re: Yeast](#)721

Are you including the rye flour in the total flour? The total flour should include only the gluten forming flours. Other flours mentioned such as spelt have a very low amount of gluten forming proteins and they create a poor quality gluten, ditto for rye flour, it appears that you are milling the steel cut wheat into a flour so that being the case it can be included in the total flour, if not milled into a flour it should be shown separately as an added ingredient. To determine the dough absorption figure 62% for the white flour portion and 75% for the dark rye flour portion, this should get you pretty close to the correct dough absorption. For the other flours use the same procedure as you would for finding the absorption of a multi-grain mix. If you search back through the archives you should find several threads of discussion on how this is done.

I hope this helps,

[Re: Help - looks like dough is being eaten from the inside out](#)722

Most cracker type doughs are made with a dough absorption of 40 to 45% and about 5% fat in the form of shortening as opposed to oil. They are mixed for a VERY SHORT TIME, usually about 2-minutes or less. The "dough" after mixing looks a lot like a biscuit or pie dough in that it is extremely "shaggy" and not cohesive at all, but instead it is dry, floury, and crumbly. The dough is scaled to desired weight and packed together on the bench top using your hands to form something that looks a bit like a puck (hockey puck), this is then wrapped in stretch wrap or placed onto a sheet pan with a 2-inch spacing between pucks and the entire sheet pan bagged or wrapped. The dough is allowed to cold ferment for a minimum of 24-hours but may go as long as 48-hours, it is then removed from the cooler and allowed to temper AT room temperature until the internal puck temperature reaches 55F, the pucks are then formed into skins using a dough sheeter or a rolling pin/pastry pin. Formed skins are trimmed to diameter and dressed for baking, usually at 500 to 550F.

[Re: Cracker style dough](#) 723

What was the total dough absorption for each of the doughs?

[Re: Help - looks like dough is being eaten from the inside out](#)724

Can you share your complete dough formulas? What I see in the photos of the

dough balls is a case of insufficient dough absorption, this is especially evident with the two rye dough balls. The stickiness you noted with the rye dough is totally normal for rye, and depending upon the strength of the white flour that you're using VWG will most likely need to be included in the dough formulation

NOTE: Depending upon the type of rye flour (light, medium or dark) the absorption of the rye flour will be something between 68 and 75%. Plus, if it's a pumpernickel rye flour it will require a soaker.

[Re: Help - looks like dough is being eaten from the inside out](#)725

You didn't mention anything about the size of the dough skin or the weight of the dough ball, this can have an impact on it too. If the problem is just due to opening technique you might want to try this to get things started:

Use a rolling pin to open the dough ball to within 2-inches of the desired diameter, then finish opening the dough by hand.

I've got a video of this procedure being used commercially. It works well and we get individuals who have never opened a dough ball by hand doing it in no time at all. Once you begin to get the hang of it you won't need to use the rolling pin anymore. P.M. me with your email address or send me an email at <thedoughdoctor@hotmail.com> and ask for the dough opening video.

[Re: center of pizza too thin....](#)726

That's more like it! ^^^

Now you can adjust the amount of dough in the rim portion when you open the skins and also adjust how far out you spread the sauce to achieve the rim you want.

[Re: Dense cornicione in a Neapolitan style pizza](#)727

One other thing I might add, have you confirmed the actual temperature of your oven using a calibrated thermometer or an IR thermometer? In many cases where one is baking directly on a stone or steel the oven door is left open for some time which DRAMATICALLY reduces the actual oven temperature at the time the pizza is placed in the oven. You can use an IR thermometer to measure the temperature both before and after placing the pizza into the oven. If you don't own one of these handy devices they are readily available from most home stores as well as Harbor Freight and online sources too. I recently picked up yet another one, this time for use in the garage, from H.F. for just \$17.00.

[Re: Crust doesn't brown](#)728

Those "industry created shortcuts" are made by fermenting flour and water to create the lactic acid and then spray drying or roller drying with sufficient temperature and time to inactivate the material. The problem is that there is primarily only one acid present, lactic, while in a naturally fermented dough or even a sourdough there are other acids present as well which changes the entire flavor profile. This is one reason why my suggestion for using these products is to incorporate some regular fermentation into the dough and use the inactive sourdough material at only 1/2 of the LOWEST recommended level and work up from there if necessary.

[Re: Article on Lactic Acid](#)729

For your next try turning the broiler on 15-minutes before putting the pizza into the oven (this is after a 1-hour pre-heat time) and increase the sugar level in your dough to 3%, or three times what you are presently using. Don't make any other changes but do record everything that you do. Let us know if this provides further improvement in crust color.

The dryness you noted in the crust is due to the par-baking of the crust. Par-baked crusts are always significantly lower in finished moisture content than single baked crusts.

After you get a baking steel you should be able to open the skin, dress it and bake it without par-baking.

[Re: Crust doesn't brown](#) **730**

I'm guessing 48-hours and 0.4% IDY.

[Re: Domino's Pan Pizza Dough Fermentation days](#) **731**

For pan pizza most go by just the risen height of the dough in the pan. Pizza Hut used to have a mark/line stamped into their deep-dish pans as an indicator of how high to allow the dough to rise.

[Re: How do I tell when dough is over-proofed?](#) **732**

At one time we used to see a lot of pizzerias blanching the green pepper slices for use in a slice operation. The reason for this is because the blanched slices do not weep (give up water) as fresh pepper slices do. They might have been using some form of canned green pepper slices but that would also be pretty close to blanched too.

Saute them as suggested will accomplish much of the same thing, something to experiment with.

[Re: cooked green peppers](#) **733**

Here is a simple trick that I've used any number of time where refrigeration was non-existent, follow your present procedure BUT withhold 1/2 of the flour and 1/3 of the water. After the dough has fermented for the desired time, on the morning that you want to make pizza add the remainder of flour and water to the fermented dough mass, mix in well, then immediately scale and ball, place dough into lightly oiled containers, lightly cover (NOT AIR TIGHT), and allow to ferment until you are ready to make your pizzas (at least 6-hours), turn dough out of the container onto a flour dusted bench, dust the dough ball on both sides and open into a skin by your preferred manner, dress and bake.

[Re: Dough balls "spreads out" to much in the box](#) **734**

CC;

Your picture graphically shows what a totally over fermented and collapsed dough looks like.

If you are to continue making pizza under those conditions you will need to reduce the amount of yeast dramatically, how much I cannot say as I don't know anything about the temperature at which the dough was fermented at but for starters I would suggest something around 0.05% (0.4-grams) CY/fresh yeast.

Now, I see that you have a question mark by the "fresh" when referencing the yeast, does this mean that the yeast is of questionable quality/freshness/age? Old yeast or improperly stored CY (stored at temperature above 40F/4.4C) can release glutathione into the dough resulting in an overly soft/extensible/weak/sticky dough. If your yeast was stored in the fridge with the broken thermostat this might be a contributing factor.

Also, I might add that if you are machine mixing, your mixing process can be made a little more direct by just putting the water into the mixing bowl, adding the yeast and then adding all of the flour and salt, then begin mixing. Your first three steps as shown serve no practical purpose with CY when machine mixing.

[Re: Dough balls "spreads out" to much in the box](#) **735**

Your family is in our prayers.

[Re: I don't ask for much.....but I ask now for your prayers.....736](#)

Bob;

Egg Shade is the coloring material used by many pizzerias in Chicago, since it's available on line and relatively inexpensive you might want to order some. Many pizzerias us 6-ounces for a 50# flour dough so you can use that to calculate the amount you will need in your dough. The darker colored dough will absorb more heat which will help with the browning of the dough.

If you can only bake at 450F can you move the oven shelf to a position closer to the heat if you have bottom heating?

Assuming you are allowing at least an hour for the oven and steel to heat before baking.

If all else fails try removing the pizza from the pan and placing it right on the steel for a minute or so to achieve a stronger bottom bake.

[Re: Chicago deep dish browning question737](#)

Your dough looks kinda dead to me so I'm guessing it's your yeast.

[Re: Dense cornicione in a Neapolitan style pizza738](#)

What you are looking at there is essentially a no-time dough or at the very best a short-time dough, neither of which will win any contests for the best tasting pizza crust. It's OK for a "feed me" pizza but that's about where that road ends. Why not just go for an over night fermentation at room temperature? If you are using IDY reduce it to 0.1% (be sure to suspend it in a SMALL amount of 95F water then add it to the dough water, no need to activate as ADY. If using ADY use 0.125% and hydrate/activate according to directions, if using CY use 0.25% and put directly into dough water and whisk to suspend then add to the mixer. Adjust the dough water temperature to 50F and allow to mix just long enough to achieve a smooth dough consistency. Divide into desired weight pieces and ball, place into lightly oiled containers and cover with a piece of foil (DO NOT SEAL TIGHTLY), place in a cool spot to ferment for 18 to 24-hours, then turn out of the container(s) onto a flour or fine corn meal dusted surface, coat the dough ball well and open into a skin by your preferred method, dress and bake.

[Re: Pizza dough in bread machine?739](#)

First things first:

- 1) Are you using a dark colored deep-dish pan?
- 2) Are you baking at an honest 525F?
- 3) Are you using margarine or Butter Flavored Crisco in the pan?
- 4) What are you baking on (stone, steel, grid)?
- 5) Do you use Egg Shade coloring in the dough?

[Re: Chicago deep dish browning question740](#)

Please explain/describe what you have including the dough formulation.

[Re: need some bread consulting, dough made, broken fridge741](#)

By all means add sugar to your dough, 2% is a good starting point but you can go higher if you want. You seemed disappointed that the 2% sugar didn't give the crust a sweet taste, pizza crust is not typically sweet tasting but if you want to have a sweeter tasting crust you have to go to at least 5% sugar for starters. If you are baking with the broiled element on that's why your cheese is getting browned too

fast. You might try moving the pizza to a lower rack position. Additionally, how long are you preheating the oven/stone? You want to preheat for at least 1-hour. A baking steel will probably help a lot.

Hand kneaded dough will always be more sticky than a machine mixed dough that is properly mixed, that's not a problem though as the condition will improve as the dough is allowed to ferment.

Your bread flour should be just fine in it is malted (check the bag).

In the mean time some things you might need to do:

- 1) Place the cheese in the freezer for 30-minutes prior to use.
- 2) Tent the top of the pizza with a piece of foil for about the first 5-minutes of the bake time (you will need to experiment).
- 3) If you are getting bubbling during baking the dough might be too cold (did not allow to warm to 55F internal dough ball temperature), par-bake with 1/2 of the sauce applied to the skin usually fixes the problem, or you may need to also dock the skin prior to dressing.

This is all based on the assumption that you are correctly following my dough formula and dough management procedure.

[Re: Crust doesn't brown](#) 742

If its just a leaven we're talking about I'd set it outside, it should be just fine.

[Re: need some bread consulting, dough made, broken fridge](#) 743

If you are running a short fermentation schedule you may need to add a little more fermentation time but if you are fermenting your dough as most of us do, 24-hours or more, you probably won't ever see the difference.

[Re: Substitute power flour for bread flour](#) 744

It is common knowledge that salt impacts yeast activity at levels above 1.5% in most dough formulations. This is addressed quite easily by an increase in the yeast level. Essentially all dough formulations which you find are already have the yeast level adjusted for the salt level to achieve a decent fermentation rate. If you want to see this for yourself just make a double size dough without any added salt, then mix until the dough comes together and forms a mass, remove from the mixing bowl, weigh the dough, divide it into two equal weight pieces, put one piece back into the mixer and add 1% salt based on the weight of flour in the dough piece, mix the dough for another 5-minutes, remove from the mixing bowl and cut off 75-grams, form into a ball and place into a lightly oiled tall drinking glass. Do the same thing with the other dough piece but add 3% salt to it, lightly tent each glass with a small piece of foil and set side by side to observe how the dough rises in each glass over the next several hours.

To see the affect of salt on gluten strength make two doughs, one without any added salt and the other with 2% added salt, pay close attention to how the gluten develops as well as how the dough feels at all stages of development.

Salt has a tremendous impact upon the taste of the baked product, when insufficient salt is used the finished product has a "starchy" taste and when excessive salt is used it has a salty taste. Some people like the salty taste while others do not, plus there are a lot of people who recognize the potential health concerns associated with excessive sodium in their diet so they try to limit sodium consumption. Salt by itself is not a flavoring but instead it should be used only to accentuate flavors already present.

[Re: Water Loss](#) 745

All of which contribute to oven spring, which without you would have nothing much more than a large poker chip.

[Re: how to get cornicione](#)746

Grease Wheel: You left the door open on this one! :-D
With GUSTO!

Artimas: Can you please describe the differences you are seeing?

There is a quantum leap between the average pizzeria and the average home kitchen when it comes to making pizza dough, but the biggest difference that I've seen is in how the dough is refrigerated. Most home refrigerators are really not all that good for dough storage as in many cases they lack the necessary refrigeration capacity but more importantly it is small in comparison to a walk-in cooler or even a commercial reach-in cooler so every time the door is opened the temperature fluctuation is significant, it may not seem so, but it is. This temperature fluctuation will have a significant impact upon the dough over the course of 24 and more hours. In many cases we can address this by targeting a lower finished dough temperature or by modifying our dough management procedure to better accommodate our unique conditions under which we make our pizzas. When teaching pizza making at homes I always tell everyone that the first thing we need to do is to have a dough formula and dough management procedure that allows us to make a decent pizza, then we need to fine tune it to allow us to make a great pizza on a consistent basis (this is a real confidence builder), after that I encourage them to experiment making different types of pizzas/pizza doughs/crusts, such as wheat, whole-wheat, multi-grain, Tex-Mex, Asian, based on thin crust or deep-dish formats (whatever their family preference is). Pizza making should be a family fun adventure in pizza cuisine, and now that we're hopefully all at home with our families this is a great time to get everyone involved in the pizza making process. My wife and I have made a pizza together for dinner for the last two days, the first one was a vegetarian topped N.Y. style and last night's pizza was a shrimp topped pizza with Alfredo sauce instead of a red sauce seasoned with dried dill from our garden last year, then we added leftover vegetables from the previous night's pizza preparation. No complaints from my better looking half! Like the old adage goes, "Happy wife, happy life" ;D

[Re: Newbie looking for a basic beginner recipe for home oven](#)747

I have to plead innocent as I know nothing about it. I've not been contacted nor informed of anything. I am sure there is a lot of confusion and work going on over this whole thing of needing to cancel Pizza Expo so when/if something falls through the cracks it is totally understandable. I give them full credit for their attempts to provide a level of training the industry desperately needs right now.

[Re: Pizza Expo/Tom Lehmann](#)748

In one word: Absolutely! IDY is no different than ADY or CY when it comes to application and performance. 24 to 48-hours is not really considered to be a long fermentation time in the realm of pizza dough. If you have a balanced dough formula and have an effective dough management procedure the amount of IDY to use for 24 to 48-hours CF will probably be in the range of 0.3 to 0.4%.

[Re: Instant dry yeast](#)749

You are confusing bakers percent and "true" percent which is based on the total dough or meat weight. To convert a dough formula into true percent just divide the

individual ingredient weights by the total dough weight and multiply by 100. The problem with using true percent with dough formulations is that if you change any one ingredient you have to go back and recalculate the percent for each of the other ingredients.

By the way, there isn't that much difference in finished moisture content between a high absorption and low absorption dough until you drop down into the 40% and lower absorption range.

[Re: Water Loss](#)750

Why would you want to do that when the salt percentage is based on the flour weight?

[Re: Water Loss](#)751

Huh? ??? ??? ??? ??? ??? ??? ???

[Re: Pizza Expo/Tom Lehman](#)752

A fully baked pizza crust will typically come in at between 22 and 28% moisture content as compared to white pan bread at 38 to 40% and pretzels which come in at 2 to 4% moisture content.

[Re: Water Loss](#)753

Your dough formula contains a SLUG of IDY as well as a SLUG of salt! I would suggest bringing the IDY down to about 0.15% and the salt down to 2% or 2.5% if you're addicted to salt. In addition to dough formulation the temperature of the room where the panned dough is being proofed as well as the temperature of the dough at the time of panning are also critical factors that enter into determining the correct yeast amount, without this information my suggestion for yeast amount should be considered as an educated SWAG.

[Re: Over night proof](#)754

Really nothing to washing it, just use a hard plastic scraper to scrape the bowl out when you remove the dough then straight to the sink where it's filled with hot water, agitator then goes into the bowl and I get back to my pizza making chores. After the dough is put up I go back to the sink and finish washing the bowl and agitator and wipe down the mixer with a damp towel. Since we are not blessed with acres of counter space I find it more troublesome to drag the mixer out from its hiding space than to wash it.

[Re: Do you mix by hand or use a mixer?](#)755

How deep are your trays?

[Re: Proofing tray storage](#)756

I use both methods. When at home I will use the KA about 3/4 of the time but when away from the house I use hand mixing almost exclusively. For small batches I can't say that I have a preference but for larger batches or multiple doughs machine mixing wins out every time.

[Re: Do you mix by hand or use a mixer?](#)757

I think two things might be responsible, too much fermentation and frying the bread at too low of a temperature. I'd suggest reducing the fermentation time to 3-hours and adjusting the temperature of the frying fat to 370F/188C. Also, I'm guessing that you are using fresh oil for frying, this is not the best to use, though you probably have little choice. Believe it or not, a blend of about 25% old frying

fat and 75% new frying fat is superior to 1% all new frying fat. One other thing, be sure to fry the items submerged.

You might incorporate these changes and let us know if you see any improvement.

[Re: Bubbles in fried dough](#)**758**

Peter;

Wow! You really did dig deep to find that one from 2003!

The SAF/Lesaffre Yeast Corporation water temperature calculation that is mentioned in the article is still available but here it is just in case someone wants it right away.

This is designed for doughs which will have a targeted desired finished dough temperature in the 82 to 88F range.

Here is the calculation:

145 minus flour temperature = desired water temperature.

While this is designed for commercial planetary mixers with a friction factor of about 30 it can be easily modified to any other type of mixer. It will take a little trial and error, but once you have it it's a handy tool to have.

- 1) Use the above equation to make a dough, measure the finished dough temperature.
- 2) If the temperature is more than 5F too high or too low recalculate the water temperature using 145 plus 10 (if the temperature is too low or 140 minus 10 if the temperature is too high).
- 3) Make a dough using the new calculated water temperature and measure the finished dough temperature. If the finished dough temperature is within 5F of your targeted finished dough temperature you're good to go, if not make another adjustment to the 145 number and repeat.

Once you have the number needed for your mixer to give you YOUR desired finished dough temperature the only variable will be the flour temperature so from that point on all you will need to do is to measure the temperature of the flour and subtract it from "your number" to get the desired water temperature.

[Re: Processor for NY Style?](#)**759**

There is an old quip that goes something like this "I'd like to help you out but I don't know how you got in", in this case I'd like to help you out but I don't have any information on what you are doing. It would be of great help if you could please provide the dough formulation and complete dough management procedure including frying conditions. I've got an idea but I really do need more information.

[Re: Bubbles in fried dough](#)**760**

With 0.3% IDY and a finished dough temperature in the 75 to 80F range I've found that 48-hours CF is needed to really develop a decent flavor, and if you can wait that long, 72-hours might be even better. In the end though the fermentation tolerance of your flour and, how well you manage your dough and YOUR specific tastes will dictate the CF time.

[Re: How to get less rise but more flavor](#)**761**

We're looking forward to seeing your progress.

[Re: Dough seems too airy after proofing](#)**762**

It's also good to keep in mind when mixing the dough that all you are looking for is a dough with a smooth appearance, once the dough takes on a smooth appearance

it has been sufficiently mixed. With time and developed expertise you will be able to better fine tune the dough mixing specific to your dough management procedure and desired finished crust characteristics, but for now I suggest just mixing for the smooth appearance. One other thing, with a food processor it is better to error on the under mixed side than on the over mixed side.

[Re: Processor for NY Style?](#)**763**

Micko;

Please post the dough formula, mixing and dough management procedure you used to make your pizza. Also, be sure to provide the finished dough temperature. I agree that 45 to 50% absorption seems awfully low, this is more like the absorption that is used to make a thin crispy type of pizza. If the ingredient amounts provided to you were in "pinches, drabs and dribbles, I think we may just need to start over fresh with a dough formula that you can manipulate to give you the desired finished crust characteristics that you are looking for.

[Re: How to get this dough? Thin crust, crispy \(but not dry\), puffy and soft inside?](#)**764**

My ALL TIME FAVORITE substitute for sauce is to use thin sliced fresh, ripe tomatoes (operative word being "ripe"). Slice about 3/16-inch thick, place on towel to remove excess juice. Brush dough skin lightly with oil, apply fresh garlic and fresh basil leaves and then apply the fresh tomato slices (don't peel) as that's where all the flavor is at. Add cheese and toppings and bake.

Let us know what you think.

[Re: Saucing with uncooked fresh tomatoes](#)**765**

"Cooked sauce, so no worries" about what?

[Re: Recanning Stanislaus Tomato Sauce](#)**766**

A good Neapolitan pizza will need to be baked at a much higher temperature (750 + F). How about a slightly modified New York style pizza formula?

[Re: Neapolitan pizza in home oven](#)**767**

I can comment on a number of things that I see here.

- 1) The salt level is low at only 1.5% I suggest increasing it to 2 or 2.5% to better control the fermentation rate. This will also improve crust flavor too.
- 2) You might want to reduce the IDY down to 0.3% (a 25% reduction in amount).
- 3) 6-hours out of the fridge before opening the dough is indeed too much, use a thermometer to measure the internal dough ball temperature and when it reaches 55 to 60F then proceed with opening it into a skin. My guess the time will be closer to 2-hours than 6-hours.
- 4) If you really want to have a thin crust you really need to use a rolling pin to fully open the dough ball into a skin and you may need to dock the skin after opening.

[Re: How to get less rise but more flavor](#)**768**

Your dough looks fine in each photograph, I wouldn't suggest making any major changes except to "make it your own". As long as you have some type of sugar in your dough you can use "00" type flours at the lower baking temperatures, but to be honest with you, I'd be highly tempted to experiment with a more typical bread type of flour rather than the "00". You might like what you get from it, but then again, you might not, try it to find out.

What is the baking time for your pizzas?

The crumb structure looks OK for what you are doing but then again,

experimentation might allow you to improve it somewhat. To go this route I'd suggest incrementally increasing the dough absorption (2% increments) to see if that helps.

I'd also experiment with ways to bake the pizza longer, perhaps try laying a piece of aluminum foil over the top of the pizza at the end of the bake and leave it in the oven for an additional minute, or so. See, now that you have a decent pizza to experiment with the real fun begins, that's what I mean by making it your own. Don't be afraid to experiment, just change only one thing at a time and record everything you do, remember, you're making PIZZA, not nitroglycerin so have fun, and remember that your mistakes can taste as good as your successes! :chef:

[Re: Need Help with Fermentation Process](#)769

Your dough really isn't a whole-wheat dough as it is only 36% whole-wheat flour, so it is more correctly referred to as a "wheat" dough. I see that your total dough absorption is 60% which might be a bit low for this type of dough as wheat and whole-wheat doughs tend to perform better at a higher absorption. My suggestion would be to make the dough again but increase the dough absorption to 65% and fine tune it from there if things look better. Keep in mind that wheat and whole-wheat doughs should be slightly tacky to the touch as opposed to dry.

You may also find that an autolyze will also help. To make the autolyze put all of the whole-wheat flour into a container with an equal amount of water, stir to suspend the flour in the water and let set undisturbed for an hour, then add it to the mixing bowl along with the remainder of the dough ingredients and mix the dough in the normal manner. You may find that this will allow you to increase the dough absorption even more for an even more open crumb structure.

[Re: 8h@RT Whole Wheat Pizza Dough](#)770

Agreed, that's some fine lookin' pizza! :drool:

Next time try something a little different by using some Crisco or some other form of plastic fat (margarine, butter, lard, etc.) on the sides of the pan and use some oil in the bottom, then bring the cheese all the way out to the edge of the pan, that'll put a Detroit twist on your pizzas.

[Re: Standard Thick Crust Recipe - Basic Pizza](#)771

Be sure to cover the deep dish pans with foil or they will dry out for sure at 110F! I can only say that IF your dough is between 80 and 85F when it is panned and set on the oven it will most likely take between 30 and 45-minutes using the dough formula I provided. We used it for over 30-years so I know how it performs, and other dough formula?

[Re: Standard Thick Crust Recipe - Basic Pizza](#)772

Andrew;

Whole wheat flour certainly qualifies as a high extraction flour, by definition it is 100% extraction. There are differences between different whole-wheat flours, for example there are whole-white wheat flours (milled from hard white wheat varieties). There are also whole-wheat flours milled from soft white wheat varieties which are referred to most commonly as graham flour. Now you know where graham crackers get their name. For this discussion we will limit ourselves to just the whole-wheat flour made from hard red wheat varieties as they are the most commonly used. There are differences in the particle size of the whole-wheat flour with "stone ground" being the coarsest, and then there is what is referred to as "steel cut" which looks like chopped/granular pieces of the wheat berry (hard to call it a flour), and then there is just a common whole-wheat flour which is what

most of us relate to when thinking of whole-wheat flour. Since you are looking at replacing a regular whole-wheat flour with a stone ground type (it isn't actually ground on a stone anymore except maybe by some small independent retail millers), Be aware that the bran pieces will be larger and exert a more pronounced cutting effect upon the gluten film, and the larger pieces of bran will take longer to hydrate so I would highly encourage you to think about using the whole-wheat flour in an autolyze. Use sufficient water in the autolyze to make a thick pasty consistency and let it hydrate for about an hour. To figure the total dough absorption use 60% for the white flour and 75% for the whole-wheat portion of the flour blend and you should be pretty close. Mix the dough just until it begins to develop a smooth skin, DO NOT OVER MIX. Target finished dough temperature will be 75 to 80F. Don't get fancy with fermentation, mix, scale, ball, cold ferment NOT MORE THAN 24-HOURS. Don't skip the cross-stacking and tempering periods after the cold fermentation and you should be fine.

I've never heard of wheat or whole-wheat items described as having a "buttery" aroma, it is almost universally described as being "nutty", however, with that said, in all of my whole-wheat dough formulas I always use butter, seldom ever oil which does indeed impart a nice buttery aroma and taste to the finished produce, especially when you have the butter (Butter Flavored Crisco works well too) up at 5% or more. Also, you may find that a wheat or especially a whole-wheat dough benefits from a slightly higher yeast level.

You should have no issues at all substituting 25 to 30% whole-wheat flour for an equal amount of white flour in your pizza dough while retaining pretty normal dough handling properties.

[Re: blending whole wheat?](#)**773**

Between 3/8 and 1/2-inch thick depending upon how thick you want the final crust to be. I suggest starting at something around 1/4-inch thick and then make another one a little bit thicker until you find what you like.

[Re: Standard Thick Crust Recipe - Basic Pizza](#)**774**

As the name indicates what you are looking at is ADY (active dry yeast). It is different in a number of ways from IDY but the main thing to remember is that when using ADY it must be hydrated and activated prior to use. Do this by putting the ADY into about 5 times its weight of 100F/38C water. Be sure to put the yeast into the water, not the other way around. The water that the yeast is hydrated/activated in should be considered as part of the total dough water. Stir the yeast to suspend it in the water. Allow the suspended yeast to set for about 10-minutes to activate, then stir and pour into the dough water in the mixing bowl, you are now ready to add the remainder of ingredients and begin the mixing sequence.

[Re: SAF IDY](#)**775**

While it can be done, I think as a novice, working with high absorption and long fermentation doughs you would be much better served using individual dough containers that have been lightly oiled.

[Re: Transferring High Hydration Dough from Dough Tray](#)**776**

Just a guess here but I'm guessing that the flour was mis-scaled, maybe only 1000-grams or the tare of the container wasn't accounted for. Try to get a weight on what you have, it might give a clue.

[Re: Standard Thick Crust Recipe - Basic Pizza](#)**777**

I don't have any "recipes" but here is a good formula for one;
Strong bread type flour (12 or 12.8% protein content) 100%
Salt: 1.75%
Sugar: 2%
Shortening (Butter flavored Crisco, butter, margarine, non-deodorized lard, etc.)
4%
IDY: 0.4%
Water: (65F) 64%
Target finished dough temperature: 75 to 80F.
Mix to a smooth dough consistency, take directly to the bench for scaling and balling, wipe dough balls with salad oil, place in individual plastic bread type bags, twist open end into a pony tail and tuck it under the dough ball as you place it in the fridge. Cold ferment for 24 to 48-hours, remove from fridge and allow to warm to 60F INTERNAL ball temperature, roll bag down around the dough ball and invert over a floured surface, flour both sides of the dough ball and using a rolling pin or pastry pin open to a diameter slightly larger than your pan. Prepare the pan by applying oil to the inside of the pan, you want to have a well oiled pan. Place the opened dough into the pan and set aside for about 20-minutes, then using your hands/fingers finish stretching the dough to completely fill the pan, drape with a plastic sheet and allow to final proof for about 45-minutes (time will be variable depending upon the thickness you want in the finished crust). Dress the skin to within 1/2-inch of the edge and bake or using your fingers, pull the dough up on the edge of the pan just before dressing. Bake at 450 to 500F on a grid type oven shelf. You may need to rotate and change shelf position after about 12-minutes of baking. Remove from pan immediately after baking.

Note: A dark colored pan or a well seasoned pan is by far the best pan to use, a 1.5 to 2-inch edge height is desirable.

[Re: Standard Thick Crust Recipe - Basic Pizza](#) 778

No, why not just pyramid stack them or lay a piece of wood (or how about a table knife) across the top of the bottom containers and then stack on top of that? Where there's a will, there's a way.

[Re: Need Help with Fermentation Process](#) 779

I can see a few things that might be creating a problem for you.

- 1) 25% (400-grams) of your total flour is a durum semolina flour which creates a very tough, elastic gluten. I would suggest replacing the durum semolina flour with your organic bread flour or the "00" flour.
- 2) You are adding 22% sourdough starter which I think is excessive, try using it at 1/2 of the present level.
- 3) You mention using the "window pane" test to check for gluten development, this is ONLY FOR BREAD, it is not used for pizza dough as pizza dough is not mixed the same as a bread dough. Instead, just mix the dough until it has a smooth appearance, more mixing than that is not needed nor desirable.
- 4) Since you have a spiral mixer I'd like to propose a different, more direct mixing method. Put water in the mixing bowl (20 to 21C), then add the starter followed by the flour (all of it), add the salt and mix until all of the flour has been hydrated then add the oil and continue mixing until the dough takes on a smooth, satiny appearance. Measure the dough temperature, it should be in the 23 to 27C range. Take the dough directly to the bench for scaling and balling, lightly oil each dough ball and place into fermentation container(s), DO NOT APPLY LIDS, leave the containers open in the fridge until the internal dough ball temperature reaches

10C then cover/lid the containers and allow to cold ferment for 24-hours (the dough will probably be at its best after 48-hours). You might want to make some pizzas from the dough after both 24 and 48-hours to see what works best for you. When you're ready to use the dough balls remove from the cooler and place at room temperature ONLY until the internal temperature of the dough ball reaches 10 to 15C, then turn the dough ball out onto a floured surface and open into a skin by your preferred method, dress to the order and bake.

Let us know how this works for you, provide some pictures if you can.

[Re: Need Help with Fermenation Process](#) 780

I wouldn't say that your time was limited in any way unless we are talking about a commercial pizzeria setting, but as the dough temperature increased after the cold refrigeration period the dough will not get any easier to work with and in fact, it might even begin to get gassy to the point where bubbles in the dough become an issue.

[Re: Cold Bulk Fermentation questions](#) 41

You tossed them out? Remember what we always say; Even our mistakes can taste pretty good too! If nothing else it would have been a good learning experience for you in opening a soft/slack/extensible dough which you might not otherwise get. :'(

[Re: Pizza Dough over rising and deflating?? Help](#) 42

I've visited a lot of different type of forums over the years and one thing that I can attest to is that pizzamaking.com is one of the most sharing (by all participants), respectful and civil of all the forums. This is in great part due to the tremendous efforts of Peter, which in my world don't go unnoticed. Pizzamaking.com, if not already, is well on its way to becoming the most recognized collective authority for knowledge for the home/hobby pizza maker in the world which is quite an achievement for all at Pizzamaking.com!

[Re: longer RT sourdough fermentation](#) 43

Manually flatten the dough on the bench as you would for shaping bread dough to make a loaf of bread (plenty of good videos on the Internet), then fold the ends in a few inches and loosely roll (about 1.5 curls) like a jelly roll, place onto a lightly floured sheet pan, lightly dust the top of the dough and cover with a sheet of plastic and allow to relax for 20-minutes, or just until the dough can be easily rolled to a thickness of 1/2-inch/12.5-mm. for immediate cutting.

[Re: adding salt too early??](#) 44

Make the dough again but next time use only 1/2 of the amount of starter. If that improves things you can begin incrementally increasing the amount of starter until you see or experience something you don't like, then back the amount down a little and that'll be the maximum amount you can use of that SPECIFIC starter.

[Re: Dough is ripping while stretching, help!](#) 45

After removing the dough from the fridge a good rule is to allow it to warm AT (NOT TO) room temperature until the INTERNAL dough ball temperature is in the 50 to 60F range. The dough will be a little firmer and easier for some to handle at the lower end of the temperature range while at the upper end the dough will be softer and more extensible and easier to open only if you possess the necessary skills to open a soft and extensible dough and peel it into the oven without creating a disaster.

[Re: Cold Bulk Fermentation questions](#) 46

A couple of things that I see;

1) I'm assuming the 80 to 85F water is for activating the ADY, but that temperature is not correct, it should be 100 to 105F.

2) You are using ice water, but what is the finished dough temperature. The finished dough temperature is what sets the stage for the fermentation that is to come. If the dough temperature is too cold the dough ferments too slowly and if too warm it will ferment faster than anticipated.

3) I see you are using a poolish, how much of the total flour is in the poolish? How much yeast? Temperature of the poolish? How long do you ferment the poolish for?

4) Hand or machine mixing?

[Re: Neapolitan crust isn't puffing up](#) 47

One of the problems you can have by putting the salt into the dough after the fat has been added (high fat doughs only) is that it can be difficult to dissolve and disperse the salt in the dough unless the salt is a very fine granulation salt. The presence of salt in the dough prior to the addition of the fat will not have any impact upon how the fat disperses in the dough.

Are you making pizza or donuts from this dough? The picture that you attached looks more like a pizza skin. Normally when we open the dough for making donuts we open it to a thickness of about 1/2-inch/12.5-mm. using a rolling pin or a pastry pin to achieve a smooth, flat surface to the top of the dough sheet prior to cutting with a donut cutter for "hand snapped" donuts.

[Re: adding salt too early??](#) 48

I'm betting that if you read the label on the bag of flour that it will not mention anything about the addition of malted barley flour or enzymes. This would be an indication that you do not have a malted flour. The two options then would be to add more sugar or to buy some diastatic malt and add that to the dough. With the malt products that you have available to you locally you will need to add between 1 and 2%.

On a different note, I'd suggest investing in a low cost scale as well as a dial/stem type thermometer, this will allow you to begin scaling your ingredients as opposed to using "estimated" volumetric portions for your "recipe". With all of your ingredients in weight measures it will be easy to convert the formula into bakers percent which will then allow you to begin making effective changes to the formula to achieve your specific desired characteristics. By weighing your ingredients you will also significantly improve the consistency of your pizzas from one bake to another.

[Re: Pale base, sad face.](#) 49

Bringing the dough balls up to room temperature after CF is probably not the best thing for you to do. Instead, allow the dough balls to warm AT (NOT TO) room temperature until the INTERNAL dough ball temperature reaches something in the 50 to 60F range, keeping in mind that the lower the temperature the easier the dough will be to handle and the higher the temperature (60F) the easier it will stretch, not a bad thing if you have the ability to work with a softer dough condition.

[Re: Pizza Dough over rising and deflating?? Help](#) 50

I neglected to mention that in these cases the dough is mixed to just short of the desired gluten development before the fat is added, failure to do so might result in being unable to achieve the desired level of gluten development in the dough.

[Re: adding salt too early??](#)**51**

When dealing with high fat content doughs it's preferable to add the salt right up front in the mixing process and hold the fat out (like with the delayed oil addition mixing method) only this applies to all types of fat, both liquid and plastic. The reason for this is because at high levels, in addition to interfering with flour hydration it also plays havoc on gluten development often resulting in atypically long mixing times.

[Re: adding salt too early??](#)**52**

When we say 100% fermentation we are saying that the dough has been fully fermented (ideally fermented) for the product being made under a specific set of conditions. For most white pan bread doughs using the straight dough procedure and a finished dough temperature of 80F. 2.5-hours of fermentation time is typically considered to be 80% fermentation. However, this can change dramatically if you have a different finished dough temperature, more or less yeast, more or less salt, or a very strong flour. This is why we seldom use this expression of fermentation anymore. The one thing that we do concern ourselves more about is the fermentation tolerance of a flour, some flours are very tolerant to fermentation while others are not. We can see this with some of the Caputo flours where not more than 12-hours of total fermentation time is recommended.

When I first started doing my research on pizza back in the mid-1960's it was thought that both bread and pizza production shared the same technology, but as we got into understanding more about pizza it was clear that pizza production had a technology of its own and it took us many years to unravel that technology.

[Re: very sticky dough](#)**53**

It's important to note that in addition to daily filtering of the frying fat and cleaning of the fryer they are adding fresh oil every day too, this is important to note since by doing so you are continually diluting the old frying fat. In commercial operations it is not unusual at all to end up replacing 50 to 100% of the fat weight on a daily basis.

[Re: How many times do you reuse your frying oil?](#)**54**

Probably not as you want a pizza dough to be more relaxed than it would be for making bread. If the dough is not relaxed (through fermentation) you will only be fighting it as you're trying to open the dough into a skin, and then if you are successful, it will most likely just shrink back in size during baking.

[Re: very sticky dough](#)**55**

QJ:

If you don't mind the garlic a bechamel sauce works well or if you want something a bit more subtle a basic Alfredo sauce can be used equally as well.

[Re: turkey pizza with leftovers?](#)**56**

I should also add that if you are mixing the dough by hand the preferred method for adding IDY is to put it into about 5 times its weight of 95F water (the temperature is critical with IDY) and all you need to do is to stir it to form a suspension, you can then add it directly into the remainder of the dough water in the mixing bowl. If you have the salt in the water in the bowl it's important that the flour be ready to be added immediately following the addition of the IDY suspension. Also, unless you're doing it for the exercise, there is no benefit to stirring the salt into the water, just dump the salt and proceed to the next step.

When it comes to making yeast leavened doughs temperature reigns supreme. Since temperature is the #1 driver of fermentation you will want to control it very closely and record it as part of your dough record keeping. For most of us, a finished dough temperature in the 75 to 80F range works well and if you're cold fermenting the dough we have some good practices for effective dough management posted here that might help you.

[Re: yeast - fresh, IDY, ADY revisited](#)**57**

Amen! With practice comes proficiency, with proficiency comes new and even more exciting things to explore along the pizza making journey.

[Re: very sticky dough](#)**58**

Walter;

Remember the the battle cry of us AARPers! Work smarter! Not harder! :-D

[Re: Rounder and divders](#)**59**

Rancidity will even occur in the refrigerator or even the freezer. If it's going to be that infrequently it's a moot issue, fry, drain and discard.

If this is for a commercial application write it off as a bad idea.

[Re: How many times do you reuse your frying oil?](#)**60**

The ascorbic acid is added only to counter the softening effect of the glutathione (yes, some is released during the drying and rehydration process).

The specific strain of S.C. used in the SAF GOLD has a high tolerance for sugar, but remember, SAF/Lesaffre is a French company so it was developed specifically for the French baking industry where low salt levels are employed when high sugar levels are used, this is why we see such limited use of it here in the U.S. as we typically use both high sugar and salt levels at the same time.

By the way, there is also a GREEN LABEL SAF which was developed specifically for use in frozen dough systems. We looked at this one too and didn't fine there to be sufficient difference in performance over RED LABEL to justify its increased cost. Again, this is why we don't see it used more than we do. You might say that it's hard to improve upon something as good as SAF RED LABEL.

[Re: SAF IDY](#)**781**

The big question though is, what are those individuals going to do once this is over?

[Re: yeast and flour supply chain?](#)**782**

Freezing, the great equalizer.

[Re: Even during a pandemic, we'll never be this hungry](#)**783**

When things normalize the hoarders will be sitting on a life time supply of unopened bags of flour. I'm betting that very few even know how to make bread and even fewer will ever try their hand at it after they can just pick it off of the supermarket shelf. Has anybody heard if there has been a run on MREs (meals ready to eat/modern day military rations)? I used to see people buying that stuff by the pallet! I think as much, if not more went to the civilian market as went to the military.

[Re: yeast and flour supply chain?](#)**784**

It sounds like you're using too much oil, just brush the top of the rim with oil, as the rim expends it will roll the sides down allowing the top to expand and become

the outer edge of the rim. The thing about oil is that a little does the same job as a lot when you're putting it on the rim before baking.

[Re: Oil in rim sticks to peel](#)**785**

Not all that well. It has a high tolerance to sugar but a VERY POOR tolerance to salt, so unless you are using 1% salt or less, I don't recommend it.

[Re: SAF IDY](#)**786**

Back in the 80's during the great pizza price wars which also brought us "extended cheese product" (they had to do something to keep the price down) and since no one thought much of the quality of a frozen pizza it really didn't matter because as mentioned, even back then people were buying the cheapest on the shelf and "doctoring" with their own toppings. I worked with a frozen pizza company (Fellini's Pizza) out of Topeka, KS at introducing the first really value packed frozen pizza (preceded Tony's Red Baron). While essentially all frozen supermarket pizzas were selling for \$1.00 each or a little less we developed and introduced an 11-inch frozen pizza that was REALLY LOADED with toppings (you could visibly perceive the value in that pizza). We sold it for \$3.00 for a single topping and \$4.00 for two toppings (in addition to cheese). For the cheese pizza we used a cheese blend along with 1/3 more cheese on the pizza (8-ounces total). The pizza was a huge success and it continually sold out at all of the Dillon's Stores here in Kansas. The television ad that was developed for it was as follows: A gurney is wheeled by a team of doctors and nurses towards the double doors of the operating room (this was shot at Stormont Vail Hospital in Topeka but when by a different name back then I believe) as the gurney approached the doors a nurse pulls back the sheet and proclaims "Wait! This is a Fellini's Pizza, it doesn't need to be doctored". Pretty corny I know, but it worked, it got the message across.

[Re: Even during a pandemic, we'll never be this hungry](#)**787**

A short time ago we discussed bulk and ball fermentation here. With such a small size dough you will not achieve any benefit to bulk fermentation. Because of this I'd suggest just balling the dough and then giving it the room temperature fermentation, then turn it out of the container onto a floured surface, flour the dough ball and open it into a skin ready for dressing and baking. You don't even have a pastry pin?

[Re: What factors influence the amount of air in the cornicone?](#)**788**

My first introduction to pizza was the Chef Boyardee home pizza kit about 60-years ago, as a kid I liked it but today it makes anything sold on a cardboard circle from a frozen case look pretty darn good but as noted, over time our tastes do change. That doesn't make them anything less of a pizza, they're just not at the top of my list anymore. But it is nice to know that when things get tough, it's not burgers and dogs, or even Mac & Cheese that people turn to in desperation, it's PIZZA! Doesn't make any difference the "ilk" of it, it's still PIZZA! :pizza: :pizza: :pizza:

[Re: Even during a pandemic, we'll never be this hungry](#)**789**

As a rule, the colder/cooler the dough is going into the oven the longer it will take to achieve the same bake as a warmer dough at the same oven temperature but this difference is all but impossible to see in anything but an air impingement oven as the difference is measured in seconds, not minutes. You can also impact the baking of the top of the pizza by using colder toppings. We were able to see differences in top bake with cold v/s warm sauce and cheese in our deck ovens at 500F more so than in our air impingement ovens at 475F. You mention that you feel

that your dough could use more water, why don't you increase the dough absorption in 2% increments to see what that does for you? A couple percent increase in dough absorption will not mandate a change in oven temperature. I normally think of pizza doughs as having a typical dough absorption in the 62 to 68% range for a N.Y. style pizza, cracker style doughs are a lot lower in absorption, typically in the 40 to 50% range with thin crispy doughs coming in at 52 to 56%. There are a good many Neo. style doughs as well as "traditional" style doughs which utilize what I refer to as high absorption (above 70%), these doughs can have an absorption of anywhere from 70 to as high as 82% with most probably falling in the 75 to 78% range.

[Re: Correlation between hydration and cook temp and time?](#) 790

From what you are describing as well as your comments on "pushing" the dough lead me to believe that you might have a problem in the way you are opening the dough. Here is something to try, open the dough using a rolling pin or pastry pin but DO NOT open it to full diameter, instead just open it to within 36 to 50mm of the full diameter, then finish opening the skin to full diameter by hand. Be sure to provide us with the dough ball weight and diameter pizza you are making.

[Re: What factors influence the amount of air in the cornicone?](#) 791

My feelings exactly! ^^^ ^^^ ^^^

Let's put this in context here, someone buys a frozen pizza from you, just how long do you suppose they are going to sit on it before consuming it? An educated SWAG says less than a week. You can freeze just about any pizza or raw dough for that matter for up to 15-days without any disastrous change in quality, so if you put a manufactured/made-on date as well as a use-by date on the package quality should not be an issue, ingredient labeling, well that's a different issue. You just want to make sure you don't sell the pizza to someone who has an allergy specific to an ingredient or topping that you are using.

[Re: frozen/vacuum sealer pizza for delivery and pickup.](#) 792

I'm not sure I fully understand your question but as far as shortages in flour and yeast are concerned it is my understanding that neither is in short supply, but there are some regional supply/distribution issues especially at the store/supermarket level. From what I've seen and heard yeast is still widely available from on-line sources, many have said the same for flour but shipping costs can dramatically increase the cost. You might check out any local restaurant supply facilities as they should have a good inventory of flour, maybe not exactly what you want but then this is a good time to learn to improvise. How long will this last? That's impossible to say but I think what we are seeing is spot shortages, none on the shelves today but they were full yesterday.

As to how often you should be baking bread and pizza, wow! That's a tough one to answer. I've got something over 200-pounds of flour on hand with plenty of yeast and baking powder so I'm pretty well set-up for the near future. Right now I bake every other day or so, bread, pizza, calzones, pies, cakes and kuchen. Yes, we have two chest freezers in the basement full of venison and pork as well as frozen and dehydrated vegetables, fruit and berries all from last years harvest so we're not in the same boat as our city brethren, the point is make what you can as often as you can with the amount of supplies you have on hand and as you're out and about on a "necessities" run keep an eye out for something you can use to justify firing up the oven. I was out this morning and I could have snagged two bags of KA Whole-Wheat Flour on the shelf or a couple cans of baking powder but I didn't.

[Re: yeast and flour supply chain?](#) 793

Not all foods are prone to clostridium contamination, clostridium is primarily soil borne, so think about things like garlic, carrots, onion, vegetables, etc as being more prone to it. Meats and fruits seem to be pretty safe but after that you're on your own. Just because something can be vacuum packaged doesn't mean that it will be safe to eat, the same can be said about canning foods too. If one wants to do something for their own family, that's fine, let's pray that nothing goes terribly wrong, but when we begin to market the product to other people, outside of our immediate family one has an obligation to ensure that food item is safe and sanitary, in my world playing Russian Roulette is not considered to be a safe activity so I'd rather see it frozen than vacuum packaged unless you have the microbiologist on staff to certify its safety.

[Re: frozen/vacuum sealer pizza for delivery and pickup. 794](#)

Chlostridium aka botulinum is not destroyed by heat as its the aflataxin that's so deadly. It can still be present after baking. Since its an anerobe it doesn't grow in the presence of air only in an anaerobic environment (like a vacuum sealed package). There have been two documented cases of clostridium in vacuum packaged tortillas and one in bread from back in the 50's. The last case of clostridium poisoning that I read about was back in the 90s? where a young housewife in Indiana canned some low acid tomatoes using a high acid tomato recipe, the entire family died. Garlic is also a good or better candidate for clostridium when added to oil.

[Re: frozen/vacuum sealer pizza for delivery and pickup. 795](#)

Restaurants, bars, pizzerias, buffets all ordered to shut down to any dine-in, only DELCO is now allowed. The places not impacted are those that do delivery only like Domino's, the various sandwich shops, and Sonic. Most are hoping to just retain staff during these trying times, profits are on the back burner for now.

[Re: how is the Corona virus affecting business? 796](#)

Again.

Only open what you need, the rest is already canned. If canning something twice would improve the product I'm sure Stainslaus would be doing it. Freeze only the remainder of the opened product, if you absolutely must, can only that portion of the opened cans. If you're worried about being able to get future product, deviate from your "norm" and use just a single product on your pizzas (desperate times call for desperate measures). I personally prefer to use just the 7/11 ground whole tomatoes (with peel) as my "go to" sauce. Another favorite is 74/40 Tomato Filets (I use the drained juice for my pasta sauce base) and the Saporito is used for what I call my "chunky" sauce.

I've been making more pizzas lately using just the frozen tomatoes from last years harvest, I drain off the juice and use the tomato for my sauce. The juice is used as a base for our next meal based on pasta. Last night I marinated a couple of chicken breasts in the drained juice then cooked the chicken in the marinade, cut it into pieces, added some vegetables (from the freezer) and cooked them in the marinade too, I then seasoned the marinade and added the cooked pasta and diced chicken, with some grated Parmesan cheese on top we had a great meal. Like I said, desperate times.....

In the end though it's your call.

[Re: Recanning Stanislaus Tomato Sauce 797](#)

Jack:

10-grams divided by 600 X 100 = 1.66% yeast. If it is ADY (active dry yeast) the level should be 0.5% or about 1/3 of what you are using. If it is IDY (instant dry yeast) the level should be about 0.375% or 22% (1/5th) of what you are using. Remember that with hand mixing the dry yeast, regardless of which type you're using should be suspended in about 5 times its weight of warm (100F) water prior to addition to the dough. If you are using ADY you will want to wait about 10-minutes for the yeast to begin to activate before adding it to the dough water but if you're using IDY all you need to do is to suspend the yeast in the water by stirring in well and then adding it to the dough water.

Check your finished dough temperature too, you will be looking for a temperature in the 75 to 85F range for hand mixed dough. This is adjusted by the temperature of the dough water.

After you take the dough out of the fridge only allow it to set out at room temperature until the internal dough ball temperature reaches 60F, more time than that is not necessary and will probably put your dough opening skills to a greater test.

[Re: Dough seems too airy after proofing](#) **798**

DO NOT vacuum package the pizza as there is a potential for clostridium. All of the commercial operations use MAP (modified atmosphere packaging) but not vacuum. If you search back through the archives you will find earlier discussion on this topic.

[Re: frozen/vacuum sealer pizza for delivery and pickup](#) **799**

I'm confused, why are you wanting to can 80-pounds of product when it is already canned? Why not just open a single can, use what you need and then break the remainder of the can down into smaller containers (about the amount you usually use in each container) and freeze? The other, unopened cans can be put away on a shelf for later use as you need it. It keeps very well.

[Re: Recanning Stanislaus Tomato Sauce](#) **800**

Why not just make a higher absorption biga? Put the water in the bowl first along with the yeast and then whisk the flour into the water as well as you can. This should give you a finished biga that will incorporate much more readily.

[Re: Need help with biga dough](#) **801**

I'm betting that the issue you're experiencing is mostly due to the agitator (dough hook) on your mixer. It is not really a reverse spiral design and it is very thin (small diameter) so it tends to drive through the dough without imparting as much stretching/kneading action that a thicker or cast agitator would impart. This means that your mixing time will need to be longer or at a higher speed if that is possible with your specific machine. In any case, try mixing your dough until the dough just takes on a smooth appearance and has an extensible skin.

Keep us posted on your progress.

[Re: Pizza dough is instable and breaks/tears apart](#) **802**

Most pans manufactured for baking, like bread, cake and sheet pans are anodized, with any other pans you will need to check the label or pan specifications.

QuertyJuan brings up a good point, if you put a drop of concentrated detergent on the pan and leave it there for 15-minutes and the aluminum turns dark or black it isn't anodized but if no change in color is observed it's most likely anodized.

The problem with raw (non-anodized) aluminum and dough is that the dough becomes progressively more acidic as it ferments and anything that is acidic or

caustic (like soap) will at the very least etch the aluminum removing any oxidation in the process and leaving a very clean surface on the aluminum. The downside is that the food can easily pick-up a metallic aftertaste due to the aluminum oxide.

[Re: Aluminum pans](#) **803**

QJ:

Excellent point but the Caputo Red should be sufficiently strong. Let's see what the "dough hook" looks like, it appears to be quite thin and if in the old "C" configuration it may not be developing the gluten very well.

[Re: Pizza dough is instable and breaks/tears apart.](#) **804**

I'm guessing that your pans are not anodized to prevent oxidation. Aluminum oxidizes quite fast and what you are seeing is most likely the oxidation transferring to the dough. Next time make sure the pans are anodized to prevent this from happening. You can still salvage the pans though by wiping the INSIDE of the pan(s) with salad oil and baking in a 400F oven for about 30-minutes. Do this twice and then treat them as you would a seasoned baking pan.

[Re: Aluminum pans](#) **805**

The dough does not appear to be very well developed even after 10-minutes of mixing, I can't tell from the pictures what the dough agitator/hook looks like, could you please send a picture of it laying flat on your work surface? Typically, a properly developed dough is mixed just until it takes on a smooth appearance which I do not see in any of the pictures. Just trying to figure out why.

[Re: Pizza dough is instable and breaks/tears apart.](#) **806**

No salt? Crust must taste awful.

Would need more information on mixing time, dough temperature and dough management procedure used.

Did the dough feel the same after 2-days than it did on the first day? I'm guessing it's related to the dough being initially under mixed but that as it fermented biochemical gluten development occurred which would toughen the dough significantly. Without more information that the best guess I can offer.

[Re: Dough with its own mind and mutated like a virus](#) **807**

Two main reasons;

- 1) The dough will open a lot easier at 60F than at 40F.
- 2) The dough will exhibit a pronounced tendency to bubble at the lower temperatures to the point where you are almost guaranteed a bubbling problem with a 40F dough going into the oven.

[Re: Cold Dough](#) **808**

Since you have two dough balls, unless you need both at the same time, use one now and let the other one go for an additional 24 hours to see which one you like the best.

[Re: 48 hrs bulk ferment - 12 hours ball ferment?](#) **809**

When comparing the nutritionals of whole-wheat flour against an enriched white flour the only difference is in the fiber/bran content of the whole-wheat flour. This is due to the fact that enriched flour is enriched to the same level of vitamins/minerals as whole-wheat flour. Comparing whole-wheat flour to a non-enriched white flour the cards are stacked in favor of the whole-wheat flour as the most nutritious part of the wheat berry is associated with the bran fraction, just

like apples and potatoes, when you remove the outer skin you also remove the most nutritious part.

[Re: Bulk Fermenting vs. Individual Balls](#)**810**

Beautiful cutter! Is it available with a 4 or 5-inch wheel? Over the years we found that the larger diameter wheels cut better in that they disrupted the top of the pizza less than the smaller diameter wheels.

It's hard, if not impossible to find a really good cutter with the larger diameter wheel.

[Re: KA Cutter](#)**811**

Your math is indeed correct. ^^^

Just remember to scald and then cool the liquid milk before using it and you're good to go.

[Re: Yeast donuts recipe?](#)**812**

Easy to do;

We have 56% absorption for the dough which represents all of the water added to the dough, so if we calculate 12% of 56% (56×12 press the "%" key and read the answer in the display) we find that if all of the liquid added to the dough was liquid milk the total milk solids contribution would be 6.72% (only 1% more than called for but still within the normal range for milk solids) so in this case we can substitute the water with 100% liquid milk and add the difference (6.72%) in water. If you want be specific and add the specified amount of dry milk powder called for in the dough formula you will need to replace 48% of the water with liquid milk then add 8% water plus 5.75% water for a total of 13.75% water in addition to the 48% liquid milk.

As far as the type of milk, it really doesn't make any difference as long as it is liquid milk ready for drinking (as opposed to being concentrated).

[Re: Yeast donuts recipe?](#)**813**

By us, here in Manhattan, Kansas Tony's brand and DiGiorno brand pizzas are the premium brands on our supermarket shelves and with each trip to the store I always check to see what is moving and what isn't, it's been a very consistent observation that many of the low cost pizzas are sold out or are in limited supply as compared to the higher priced/premium brands. My Econ. 101 class explained that by stating that the more expensive something is the fewer will be sold, which explains why we see more Fords on the road than Rolls Royce. :-D

[Re: Even during a pandemic, we'll never be this hungry](#)**814**

I've seen the same thing but what I'm seeing is that only the higher priced pizzas are left on the shelves, all of the Roma's, Tombstone, and other "bottom feeders" are gone. Wonder what pizzas were on either side of the Tony's? They're gone, just stating an observation.

[Re: Even during a pandemic, we'll never be this hungry](#)**815**

High heat treatment is the only one to use for yeast leavened products, any of the others can be used for chemically leavened products. Due to its cost, today many bakeries don't use dry milk powder in their yeast leavened products, instead they will often use milk replacers/substitutes designed specifically for that application. The function of the milk powder in the yeast raised donuts is to help retain moisture, contribute to crust color development, and impart flavor. The calcium content also functions to help buffer the acid formation during fermentation which

is part of the flavor improvement achieved with the use of milk.

Am I missing something? I fail to see an issue here, if high heat treatment aka bakery grade dry milk powder is not available all one has to do is to use liquid milk and heat it just until it begins to boil (scald it) then allow it to cool and use it as part of the total liquids content, just remember that liquid milk is approximately 12% solids, the rest being water. This is what bakeries and home bakers did before high heat treatment milk powder became available.

[Re: Yeast donuts recipe?](#)**816**

Alex;

I'd say that is a pretty fair summary as I see it.

[Re: Bulk Fermenting vs. Individual Balls](#)**817**

Absolutely! It only needs to be opened once after you put the dough balls in to introduce enough warm air to form a skin. In some cases a skin might form but it will only be a dry (not crusty) skin which isn't too much of an issue but if you want to address it you can always drape a damp towel over the containers for the cross-stack period, that should fix the problem regardless if the door is opened or not.

[Re: Coating dough balls in oil for high temp bakes](#)**818**

They are one and the same, just of a finer consistency.

[Re: Yeast donuts recipe?](#)**819**

Alex;

I think you hit the nail right on the head! The protein level indicated for a whole-wheat flour can be misleading, because there is about 1% protein bound to the bran portion of the flour the total protein content of a whole-wheat flour is about 1% higher than its white flour counterpart BUT that 1% extra protein is not typically comprised of gluten forming proteins so it doesn't do anything for the strength of the flour. If you cannot find a higher protein content whole-wheat flour you can always add VWG to the existing whole-wheat flour, the amount to add should raise the total protein content of your flour by 3%, since 1% VWG increases the protein content by 0.6% you will need to add about 5% VWG plus the necessary extra water $1.7 \times 5\% = 8.5\%$ extra water.

By the way, just because the spelt flour has 14% protein content doesn't mean that it's all gluten forming protein, I seriously doubt that it will work for you without the addition of VWG.

[Re: Bulk Fermenting vs. Individual Balls](#)**820**

Looks like a winner to me! :drool:

[Re: First Attempt at Lehmann Dough - The Results w/ Photos](#)**821**

Thin dough skins and extra heavy on the toppings is not a good mix for a number of reasons. If it were me, I'd be making the dough a little thicker (same diameter but greater dough weight), also you can try placing those cherry tomatoes sliced side down on a clean towel to remove some of the extra moisture from the cut surface. I do this all the time when I use nothing but sliced fresh/ripe tomato for my "sauce". You might also consider applying a very light application of oil over the center of the skin before adding the sauce, this will help to create a moisture barrier keeping the moisture on top of the skin rather than allowing it to soak into it or worse yet, through it.

[Re: Thinning Dough](#)**822**

A good temperature to final proof the dough balls at would be between 70 and 75F/21.1 to 23.9C. so your 24C location should work fine.

When re-rounding the dough don't try to make them into cannon balls that Napoleon would be proud of, instead lose round them (just get them into a round shape) and I think you will be OK.

[Re: Pizza dough is instable and breaks/tears apart.823](#)

Good point! I was assuming he was using KA Whole-Wheat flour (14% protein content) as he alluded to, but then.....maybe someone needs to pin a tail on me. :-D :-D :-D

[Re: Bulk Fermenting vs. Individual Balls824](#)

Like with everything, there is always a possibility. I can say that in many cases too much oil is being added to the dough ball which is why I always emphasize wiping a light coat of oil onto the dough balls. If you can see a shine on the surface of the dough there is sufficient oil to do the job at hand. The next time you make dough apply the oil as sparingly as possible to see if that has any impact. In some cases we've found that oil is only needed on the top of the dough ball, it is not needed in the container. For whatever reason with some containers the dough does not seem to adhere very well and it will fall free from the container with minimal distortion. Here's another trick you might try to see if it works for you, as you round the dough place the balls on the bench and lightly dust the top of the dough balls with flour (I like to use semolina flour but try your regular flour too), then place the dough balls into the un-oiled with the floured (top) side down, very lightly oil the top of the dough balls and CF as usual. Now, here is something else to ponder, according to the laws of physics (hard to argue with them) cold air holds less moisture than warm air so contrary to popular belief, things DO NOT dry out due to being placed in the fridge.....UNLESS YOU KEEP OPENING THE DOOR which allows warm air to enter which is the culprit when it comes to drying out the dough balls. If you have a dedicated fridge for the dough balls or if you can resist the temptation to open the door UNTIL YOU ARE READY TO DOWN-STACK/COVER THE CONTAINERS you might find that you don't even need to use any oil. Where the oil application is essential is in commercial practice where the dough boxes are placed into a common walk-in or reach-in cooler and the door is constantly being opened and closed plus there is significant airflow to provide a consistent temperature throughout the cooler (this is not present in a home fridge, at least none that we have ever owned), so there are some things for you to explore. Please let us know if any of these work for you.

[Re: Coating dough balls in oil for high temp bakes825](#)

When it comes time to open the dough balls don't be afraid to use dusting flour, after getting the ball pretty well opened place it on a wood prep peel with some fine corn meal as peel dust, finish opening and dress to the order, bake immediately. Let us know how it turns out.

[Re: Is this dough going to work...?826](#)

Alex;

If you are following the dough formula and procedure as shown in the video I would suggest that you look at incrementally increasing the % of yeast used in the dough formula to achieve a more open crumb structure.

What do you mean by: "That towel technique" to open the dough balls into skins? You also say that your crust burns quickly in your oven, have you confirmed the ACTUAL temperature of your oven using something like an infrared thermometer?

You mention that the dough is elastic when you go to open it, is it REALLY elastic or do you mean extensible. Elastic is like a rubber band, where you stretch it out and it pulls back or fights you as you try to open it. Extensible is when the dough is easy to open and stays put/retains its shape when you place the skin on a peel. This is an important distinction as a whole-wheat dough that is too elastic might actually be under absorbed. Most whole-wheat doughs will require about 75% total dough absorption, your total dough absorption is less than this so it might be something to consider.

[Re: Bulk Fermenting vs. Individual Balls](#)**827**

Because you get better gluten development at the higher "kneading" temperature. Isn't that why we are kneading the dough? ??? The lower temperature at the time of opening the dough ball(s) into skins serves two purposes, one is that it makes the dough easier to handle and form into a skin and two, it allows for a broader window of time to use the dough in. This is especially important in a commercial (pizzeria) setting. Most pizzerias target their opening temperature for 50F but for home application where we are only opening a couple of dough balls within a fairly short period of time we can use a higher temperature which is typically around 60F BUT keep in mind that a warmer dough can be more problematic to open if one is not skilled in opening the dough balls into skins so for home applications I will frequently suggest beginning to open the dough balls into skins at 50F and as your level of ability increases begin increasing the temperature at which you open the dough. A really skilled bench person can open doughs as warm as 85 to 90F without too much of a problem, but as we all know, many home pizza makers are not yet at that skill level. As the old adage goes: "Different strokes for different folks."

[Re: Questions about temperature?](#)**828**

Alex;

After mixing the dough what does it feel like? Select one: Dry, Tacky, Sticky, Smooth.

What is the temperature of the dough after mixing?

I see that you are using "dry yeast" what kind of dry yeast is it? Select one: Active dry yeast, Instant dry yeast.

How are you adding the yeast to the dough?

Have you tried making your dough without the honey? Honey will contribute to a darker crust color and possible burning at high baking temperatures.

[Re: Bulk Fermenting vs. Individual Balls](#)**829**

Sure, 100% bread flour will work just fine. If you notice, I have the "Crisco" shown in brackets to give an example of what is meant by All Purpose Shortening, any non-emulsified all purpose shortening will work just fine in this application.

[Re: Yeast donuts recipe?](#)**830**

To answer your questions;

- 1) What you are describing is a type of autolyse (I use an almost identical method when hand mixing the dough all the time) which is well recognized as being beneficial when hand mixing and kneading the dough as it allows for better dough hydration.
- 2) You will ALWAYS get a more consistent dough if you go directly from mixing/kneading to scaling, balling and into the fridge/cooler.
- 3) While there is a difference in crust flavor between R.T. and C.F. we have never been able to distinguish a hybrid flavor resulting from the use of both. Take your

pick, which do you like and go for it. I do realize that both methods are frequently employed and in cases I've recommended it myself but it has always been for a dough management reason not to develop a specific flavor profile in the finished crust.

4) We have investigated that and found just too many variables to draw any significant conclusions. Included in the variables are flour protein content, fermentation tolerance of the protein, dough absorption, dough formulation, dough temperature and ambient temperature. Conclusions COULD be drawn from a specific dough formula produced under controlled conditions with a specific lot of flour but in reality the data wouldn't be all that useful as the results would change with a different lot of flour (flour is NOT consistent) as well as with any change in the finished dough temperature and if your dough formula wasn't the same as that used to develop the data again it wouldn't be relevant.

[Re: Proofing dough before/after cold ferments?831](#)

I'm not sure exactly what you are trying to accomplish, but if it's to look at the baking properties of different doughs you have to put something on top of the skin during the baking process as the baking dynamics are totally different for a plain skin (we'd call it a par-baked skin). The easiest thing to do is to just sauce the skin and then bake it by your preferred method, the results which you see should translate pretty well to a fully dressed pizza baked under the same conditions.

[Re: Newbie Pizza Dough Cooking Test832](#)

They are essentially the same, but the milk powder must still be heat treated for bakery application. If the product is intended to be reconstituted for drinking or cheese manufacture it is not a heat treated dry milk product. You will need to contact the manufacturer to find out if the milk powder has been heat treated for bakery applications. You might also check around at some local retail bakeries to see what kind of milk powder they're using in their yeast leavened products. When I had my shop we used to make the dough and cut the donuts on one day and then place the cut donuts on parchment lined sheet pans which were placed in the cooler, on the following morning they were removed from the cooler and placed onto proofing screens and then placed into the donut proofer for final proofing before frying. This allowed us to have yeast raised donuts ready for sale about 1.5-hours sooner than if we had to make the dough that morning. The dough will only be good for 1-day.

A 10-L mixer should work well to get you started.

[Re: Yeast donuts recipe?833](#)

I don't know anything about the dough formula he is using but you might want to try adding VWG (vital wheat gluten) to the dough formula. I would suggest starting with a 5% addition and then working up in 3% increments from there. Remember to blend the VWG into the flour to prevent pilling and also remember to increase the dough absorption by 1.7% for each 1% VWG added. The other option to look at is the use of Ultra Grain whole-wheat flour which while still whole-wheat flour has significantly different handling properties than the more conventional whole-wheat flours.

[Re: Bulk Fermenting vs. Individual Balls834](#)

To answer your questions in the order presented;

1) The type of mixing greatly factors into the heating of the dough during the mixing process, as a very general rule, the slower the mixing action the less heat build up there will be due to friction between the bowl and the dough BUT in some

cases this can be offset by a significantly longer mixing time which can result in significant heat generation.

2) Wheat proteins disassociate (come apart) at warm temperatures which is why a dough will be extremely soft and sticky at temperatures approaching 100F this softer and more extensible dough will not exhibit the same amount of bowl friction as a cold dough which is much firmer/stiffer. Cold doughs do not hydrate or develop gluten as well as warmer doughs do so you might say that a compromise temperature (the Goldilocks Temperature Range) of 70 to 85F provides doughs which will exhibit rapid flour hydration combined with good gluten development and decent handling properties.

3) 1F per hour on average.

4) Yes and no, a higher protein flour will typically be a stronger flour which will require more fermentation to give a finished dough that has the desired dough handling properties. Since temperature is the driver of fermentation one of the things that we can do is to increase the finished dough temperature to achieve a faster fermentation rate, hence more fermentation within any given period of time. With that said, we can also simply allow the dough to ferment for a longer period of time or even increase the yeast level. Each of these has pros and cons which will influence which is the most appropriate action to take based on the dough management procedure we're using.

5) I'm not sure what you mean by "enabling the yeast" but sugar hydrolyzed into nutrient for the yeast to feed upon during the fermentation process (any residual sugar is utilized in the browning reaction to provide crust color and in some cases flavor). It is well known that small amounts of sugar (about 2%) have little impact upon the fermentation rate but at higher levels the osmotic pressure exerted by the sugar upon the yeast will actually have a suppressing effect upon the fermentation rate, however at the same time it can also provide sufficient nutrient to allow for longer fermentation periods if necessary. Salt has a suppressing effect upon yeast activity. At levels above 2.25% we begin to see this, and at 3% and above the impact can be significant. Increasing the temperature will have no impact upon the yeast in this case so the usual action taken is to increase the yeast level.

6) No.

7) 34 to 40F (most will target for 36 to 40F)

8) 50F for a pizzeria and anything in the 50 to 60F range for home pizza making.

[Re: Questions about temperature?835](#)

What disappointing characteristics have you been finding? Remember that different mozzarella cheeses will perform differently under different baking conditions.

[Re: Spotting LM Mozz from the nutrition label?836](#)

We developed that procedure for use with commercial frozen dough which is made without any kind of fermentation at all (fermentation before the freezing process is detrimental to long frozen shelf life properties of the dough) so it's awful in the taste and aroma department when it comes to the finished/baked crust. That procedure actually provides a pretty decent flavor to the finished crust, at least when compared to the alternative.

[Re: Specific Dough Freezing Question837](#)

When you are mixing your dough with a mechanical mixer it is not necessary to allow the dough to rest at any time during the mixing process. Your math is correct. ^^^

[Re: Pizza dough is instable and breaks/tears apart.838](#)

The problem stems from the use of 100% whole-wheat flour, you will not get an extremely open crumb structure as you do when using white flour. By nature whole-wheat items are more dense than those made with white flour. This is due to the roughly 20% bran content of the whole-wheat flour, it absorbs a lot of water and it has a cutting and disrupting effect upon the gluten structure neither of which is conducive to a very light, open crumb structure. Whole-wheat flour is best when used to make relatively thin crust pizzas if any kind of crispiness is desired. It can be used to make thicker crust pizzas as well as pan style pizzas but crispiness is generally not going to be a strong point.

I've had my best whole-wheat pizzas when baking at 260C both top and bottom. At this temperature I can bake the pizzas sufficiently long to get the crust thoroughly baked without burning the top of the pizza.

[Re: Bulk Fermenting vs. Individual Balls](#)**839**

Gus;

You might try leaving the door cracked open a bit during the last part of the baking process to allow for ventilation of some of that steam out of the oven, this should give you a crispier finished pizza if that is your quest. Otherwise, steam will give you a soft and soggy pizza.

[Re: Steam oven](#)**840**

Nope, scale and ball the dough immediately after mixing. The dough will feel soft and tacky but don't let that discourage you as it will improve during the fermentation period. No need for stretch and fold as biochemical gluten development will take the place of that for you.

[Re: Bulk Fermenting vs. Individual Balls](#)**841**

When you go to use the frozen dough place it in the fridge overnight to slack-out/thaw, then bring it out to room temperature and allow it to warm to about 55F internal ball temperature before opening it into a skin for use.

Another good way to manage your frozen dough is to make the dough with little to no fermentation time prior to freezing it, then in preparation for use, slack it out in the fridge overnight, then bring it out to room temperature until the internal dough ball temperature reaches 55 to 60F, reball it, lightly oil the dough ball and place into individual plastic (bread type) bags, twist the open end to close and tuck the pony tail under the dough ball as you place it back into the fridge to cold ferment for 24-hours. Remove from fridge and allow to warm to 55F (internal ball temperature), then roll the bag down around the dough ball and invert it over a flour dusted bench/counter top, or bowl of flour, flour the dough ball and open into a skin by your preferred method, the skin will be ready for immediate use.

[Re: Specific Dough Freezing Question](#)**842**

I don't know what you mean by "will the outer skins be OK" If you are suggesting placing the dough balls onto sheet pans for freezing no problem, I do suggest that you flatten them to about 2-inches or so as this will greatly reduce the time needed to freeze the dough ball to the core. In large scale production we usually lightly oil the dough balls (pucks as they are referred to as) prior to freezing as this is another step in making sure the dough balls don't stick together when bulk packaged. The dough does not dry out in the freezer IF the freezer is kept closed. Keep in mind that unless you are either mechanically freezing at -25F (ideally lower) or cryogenically freezing at -40 to -55F your shelf life of the frozen dough will be limited to about 2-weeks.

[Re: Specific Dough Freezing Question](#)**843**

I always like to investigate the easy things first so what I'd suggest is as follows:

- 1) Add the cold water to the mixing bowl then add the sourdough (if used) to the water followed by the flour, yeast (if used) and salt.
- 2) Mix the dough longer than what you are presently mixing for, you want to mix until the dough has a smooth appearance.
- 3) Scale and ball the dough immediately after mixing, place it into lightly oiled containers but DO NOT COVER/LID as tightly as you are presently doing. The dough will release carbon dioxide gas which will blanket the dough preventing it from drying out. Cut a couple small holes in the plastic wrap to prevent any pressure build up in the containers.
- 4) After the room temperature fermentation period reball the dough placing the dough balls back into their containers and cover lightly.
- 5) Allow the reballed dough to rest at room temperature for about 5-hours or until it can be easily opened into a skin.

Try this and let us know what the results are.

[Re: Pizza dough is instable and breaks/tears apart.](#)**844**

Can you please share your dough formula and dough management procedure with us? Also be sure to include all dough temperatures.

[Re: Help with Tough Dough/Crust](#)**845**

Since you asked, here is what I would do;

After the initial counter top bulk fermentation, divide the dough into desired weight pieces and form into balls, wipe the balls with oil and place in the cooler without a lid on the container(s) and allow it to cool to 50F internal ball temperature, then lid/cover the container(s) and allow to CF for the additional time. Remove from cooler, allow to temper AT room temperature until the internal dough ball temperature reaches 55F then begin opening the balls into skins by your preferred method. Dress and bake.

[Re: Is this dough going to work...?](#)**846**

Gus;

I need a little more information on the oven, it sounds like it is a steam injected oven using low pressure steam and gas or electric to heat the oven. A rotating rack oven with steam injection would be a good example of this type of oven. For baking a pizza on a raw dough skin this would probably not be a good choice but for reheating a pizza or a slice it might work OK if the steam can be controlled and evacuated from the baking chamber to allow for crisping of the pizza after it has been reheated.

[Re: Steam oven](#)**847**

We're talking about two different things here right? Gummy bread and pizza crust and the development of a gum line in a pizza crust. Flour has three main parts, starch, protein and moisture. There is typically less than 1% ash and minerals. The starch has very little capacity to carry water as it is in the flour so the burden of carrying the water is left up to the protein, the more protein present the higher the dough absorption. As the dough is baked/heated the protein gives up the water to the starch which is beginning to gelatinize and now has a high affinity for water, the starch gelatinizes/sets and creates the structure for the finished product we're making. A higher protein content doesn't hold on to the water any differently than a lower protein content.

[Re: Gum line](#)**848**

All of the above.

Eggs (whole eggs) add richness to the finished crust and contribute to crust color development.

Mashed potatoes contribute softness and some crust color to the finished crust. Semolina flour will help to produce a crispy thin type crust BUT at levels above 25% it will contribute to a very tough and chewy eating characteristic in the finished crust, especially after a few minutes out of the oven.

[Re: Has any one used eggs, mashed potato's or fine semolina flour to your dough?](#)**849**

The surface is pretty normal for a no knead dough. Actually, no knead doughs do get kneaded but not very much. After you knead the dough for a minute or so you will see the surface become a lot smoother as the dough again expands.

[Re: Is this dough going to work...?](#)**850**

What you've described sounds about right to me for that procedure. I use a different procedure where I grasp the skin with my palms facing down and I pull the edge of the skin between my thumb and index finger stretching the dough as I pull it through, this helps to increase the circumference of the skin.

[Re: Stretching/ opening a dough ball problem](#)**851**

Peter;

The flour needs to be frozen (not just in the freezer) for a minimum of 30-days so I'm assuming a week to allow the flour (regardless of the amount) to get down to freezing temperature. Flour is really hard to cool due to its low moisture content as well as its density.

[Re: All Trumps- unbromated, unbleached](#)**852**

There are two reasons for freezing the flour, it dramatically slows the oxidation rate and if you freeze the flour for a minimum of 30-days you will effectively kill any insects, larvae and eggs that might be in the flour. This means that a 5-pound bag of flour will need to be in the freezer for at least 6-weeks. Once frozen you can transfer it to an insect proof metal or plastic container for long term storage. It will oxidize but at least it won't be infested. Oxidized flour behaves very much like bromated flour just in case you're wondering.

[Re: All Trumps- unbromated, unbleached](#)**853**

What is the internal temperature of the dough ball at the time you begin to open it into a skin? Most pizzerias target for 50F but many home pizza makers target something in the 55 to 60F range. I'm thinking that an hour out of the fridge might not be long enough to give you this dough temperature. Also, how long are you cold fermenting the dough?

[Re: Stretching/ opening a dough ball problem](#)**854**

And let's not forget that a few years ago free form pizzas were popular too, Pizza Hut's Big Foot pizza was a good example of a commercial attempt at this.

[Re: How to make pizza perfectly round?](#)**855**

Having your A.T. flour unbromated really doesn't hurt a thing unless you are planning to ferment your dough for the better part of a week, and even then it would be questionable. As for it being malted, at the temperature you're baking at

it shouldn't pose a problem in the 700 to 750F range. You can always repackage what you don't use into 2 to 5-pound bags and freeze it. Frozen it will keep forever and a day.

[**Re: All Trumps- unbromated, unbleached**](#)**856**

The most common things that might be responsible are:

Baking too hot or not long enough.

Pre-saucing.

Over thinning of the sauce.

Using too much sauce.

Too much/many toppings.

It would really help to be able to see the issue and know more about how the pizza is made and baked as this can help in determining the cause.

[**Re: Gum line**](#)**857**

A number of years ago there was a pizzeria just outside of Pittsburgh, PA (School Hill?) that I had visited where the owner mixed all of his doughs totally by hand.

Interesting observation: The owner didn't have a hair on either of his arms or hands, if I remember correctly, he was bald too, but I don't think that had anything to do with mixing the dough :-D

[**Re: Differences between human vs. machine made pizza?**](#)**858**

OMG! We have covered this a number of times before and I've written a comprehensive article on the topic (maybe Peter can direct you to it?).

The first thing to do though is to make sure you REALLY have a gum line and not a false gum line. Turn the slice upside down so the bottom crust is facing up, use a VERY SHARP serrated knife or a single edge razor blade and using multiple strokes cut the slice from the point to the outer crust, now fold the slice so toppings are facing each other, look immediately under the sauce, if you see a gray area more than about 1/8 inch in thickness, congratulations, you have the dreaded gum line (read about how to solve) if not, don't worry as you don't have a gum line. Note: If you cut the slice from the top down, through the sauce and toppings you will ALWAYS get a false gum line as you are pulling the sauce down into the crust as you cut it. You CANNOT use a pizza wheel or rocker knife to cut the slice when looking for the presence of a gum line as these tools will compress the crumb structure making it impossible to identify the presence of a true gum line.

[**Re: Gum line**](#)**859**

It will be in the 8 to 10-minute range using 2nd. speed.

[**Re: Hobart A120 Mixer Input**](#)**860**

We studied hand v/s machine dough mixing many years ago, mixing a dough by hand is so gentle that it is all but impossible to over mix a dough without the aid of a reducing agent such as L-cysteine or glutathione aka dead yeast, machine mixing on the other hand, if it can be set to mix the dough at relatively high speed/r.p.m. can/will easily over mix just about any kind of yeast leavened dough. Because of the force applied to the dough through the mixing action the dough will heat up considerably more with machine mixing than with hand mixing as a result of bowl friction. Gluten development is considerably faster with machine mixing and there is also much better incorporation of ingredients into the dough with machine mixing. It is also a lot easier to incorporate higher levels of water into a dough with machine mixing as opposed to hand mixing/kneading. With all of this said, there

are also dough mixers that are designed to emulate the hand mixing process, the one which immediately comes to mind is the Artofex twin arm dough mixer. These mixers were designed specifically for mixing very soft/slack Danish doughs but they also work well with the higher absorption pizza doughs too. The main function of the Artofex mixer is to allow for the development of a dough without excessive gluten development. There is a very slight "chemical" if you want to call it that, difference between mixing with a planetary mixer and mixing by hand, in a planetary mixing bowl if is possible to have a limited amount of oxygen in contact with the dough so as gluten bonds are broken they are not readily reformed through oxidation at the S-H bonding points. This is one reason why it is possible to almost liquefy a dough through excessive machine mixing and it is also a contributing factor to the shorter mixing time in this type of mixer. Note that this is only observed in doughs which have been exposed to fermentation such as a remixed straight dough process or more commonly a sponge and dough process, in both of these cases the dough or sponge beings carbon dioxide into the mixing bowl and being heavier than air, it is not displaced very well by the mixing action but it does displace the air/oxygen from the bottom of the bowl where the dough is resulting in the dough being mixed in an oxygen depleted environment. We didn't see any evidence of this when we just added the ingredients to the bowl and began the dough mixing process as many of us do when making our doughs by the conventional straight dough process.

The British Tweedy Bread Mixer utilizes this principal by pulling a vacuum in the mixing chamber for significantly reduced dough mixing times. In our research we were able to achieve only a limited reduction in dough mixing time by flooding the mixing bowl with carbon dioxide during the mixing process which we attributed to the significant amount of air contained within the flour and other dry ingredients in the mixing bowl and the fact that the dough reached the desired amount of gluten development before a significant reduction in mixing time could be seen.

[Re: Differences between human vs. machine made pizza?](#) **861**

Most antacids as well as different forms of baking powder will contain aluminum.

[Re: Aluminum pans for Chicago deep dish](#) **862**

I agree with the dough absorption increase. See if it will carry 65% if its a N.Y. style that you are after.

[Re: Switched ovens, pizza is very dry and crispy now.](#) **863**

What kind of surface were you baking on in the home oven? Why the sudden increase in baking temperature?

[Re: Switched ovens, pizza is very dry and crispy now.](#) **864**

This was a very smart move on their part especially when considering the C-19 situation in Italy and Europe, not to mention Asia as well as progression along the entire West cost of the U.S. Always better to be safe than sorry.

Hopefully this thing will be behind us by the end of June!

[Re: Pizza Expo 2020 ***POSTPONED***](#) **865**

I've used the Ankarsrum mixer (a friend of mine had one) for making bread doughs but never for making pizza doughs and I've never physically or mentally done a comparison of the two mixers (the other being a planetary type mixer) so I'm probably not the best person to ask about a comparison of the two. The best I could offer is that the Ankarsrum mixer is really a home type mixer while the Hobart A-120 mixer is designed for commercial applications. With that said, there was a

period of time (mid 1970's to sometime in the 1990's when Hobart didn't make the motors for their A-120 or A-200 mixers) which left these two mixer models grossly under powered for their size. Now, if we are looking at either an A-120 or A-200 mixer made prior to that it's a whole different story as those were true work horses and didn't have to "stop for a rest" half way through mixing a large size dough.

[Re: Hobart A120 Mixer Input](#)**866**

You're not missing anything, you can get up at about 10-pounds of dough into the 12-quart bowl but but you can't achieve a consistent mix throughout the dough using that much dough with the relatively short mixing time employed for pizza dough as compared to a bread dough which is significantly longer. If you don't mind having a dough that is inconsistently mixed you can use a lot more dough than I suggested. If you don't see the dough being turned over during the mixing process you're not getting a consistent mix throughout the dough. Bread doughs are a different matter as they are mixed much longer and to a higher level of gluten development which helps to turn a larger dough over in the bowl during the mixing process. If you mix large size pizza doughs your best bet will be to stop the mixer periodically and manually turn the dough over in the bowl a couple of times during the mixing process. To your point, I should have mentioned this.

[Re: Hobart A120 Mixer Input](#)**867**

By the way, that's a very good price on the A-120 mixer, especially with all of the extras. Be sure to set the bowl to agitator clearance before using it though. The bowl lift is adjustable, place a nickle between the bowl and the reverse spiral dough arm as a gauge with the bowl in the fully up position, adjust the gap so the agitator JUST clears the nickle. If your bowls are tin plate DO NOT mix sauce in them unless you are fond of a funky metallic taste. Not a problem with stainless steel bowls. NOTE: Match bowl with agitator and mark them so they can stay together as a pair. If you heat the familiar Hobart "tink, tink, tink" as the mixer is running with or without a dough in it the clearance between bowl and agitator is not correct OR there is a dent in the bowl which has to be removed. We have discussed all of this previously here so you might want to take a stroll through the archives if appropriate. P.S. BE SURE TO BOLT YOUR MIXER DOWN as they have a tendency to want to walk off of bench tops while running.

Congrats on a great find!

[Re: Hobart A120 Mixer Input](#)**868**

I'm not personally familiar with the speed control for the conveyor but the conveyor drive motor usually isn't anything special so it might just be a rheostat type of control which should be a pretty easy fix if it is. You might search the Internet to see if you can find an electrical schematic for the oven as that will tell you for sure what you're up against.

[Re: Anvil Conveyor Oven - Belt Speed](#)**869**

Just remember to allow time for the dough ball to warm AT (repeat AT) room temperature until the internal ball temperature is in the 50 to 60F/10 to 15.5C range before opening into skins.

[Re: Fermentation time counting question](#)**870**

No, I'm saying that if you do the math as indicated and divide the total dough weight in grams by your unit weight that would be the approximate number of units that could be had from a single dough made in the A-120 bowl. I say "approximate" as there will be some bowl loss resulting in the actual dough weight

being a bit less than the calculated dough weight. You are on the right track though.

[Re: Hobart A120 Mixer Input](#)871

You would find then to be about the same with the one having the potatoes being possibly more sticky.

[Re: pour all of the water vs little by little](#)872

Powdered sugar is only necessary when you don't want to have the potential grittiness of the granulated sugar (that's why it is also known as "icing sugar" since this is a mute issue in the dough you can just use granulated sugar, a fine granulated sugar such as "fruit granulation" is most commonly used in bakery applications.

[Re: pour all of the water vs little by little](#)873

With a 65% absorption dough the A-120 (12-quart capacity) mixer will handle up to a maximum of 1,000-grams of total flour weight. I used them all the time when I ran the bake lab at AIB. Add up the total of all the bakers % (find the sum) then divide by 100 and multiply the 1000-gram flour weight by this to find the total dough weight. It will probably be close to 170 divided by 100 = 1.7 so 1.7 X 1,000 = 1700-grams total dough weight.

[Re: Hobart A120 Mixer Input](#)874

In most large wholesale bakeries where sweet dough is made the sugar is held back in the dough mixing process along with a good portion of the fat until the gluten has been pretty well developed to the desired point, the sugar and fat are then gradually added and mixed in just to get a thorough incorporation.

[Re: pour all of the water vs little by little](#)875

In all probability not, just reball the dough and place it back into the fridge, then about 3-hours before you plan on using the dough remove it from the fridge to temper AT room temperature. The dough balls will be ready to use when the internal temperature of the dough balls reaches a temperature between 50 and 60F.

[Re: Yeast doing too much work.](#) 876

Here is some direction;

- 1) Use a strong bread type flour and mix the dough to just short of full gluten development.
- 2) Dough absorption will be about 56%
- 3) Dough formulation will include the reducing agent RS-190 aka dead yeast to reduce mixing time and provide extensibility to the dough.
- 4) Target a finished dough temperature in the range of 80 to 85F.
- 5) Very little fermentation time is employed in making this crust.
- 6) To form the skin use a dough sheeter/rolling pin or pastry pin.
- 7) After forming, dock the skin and allow it to proof for 15-minutes before baking.
- 8) Bake at 425F
- 9) Here's a starting dough formula if you don't already have one;
Flour: 100%
Salt: 2%
Sugar: 2%
Oil: 2%
RS-190: 1.5%

Ticaloid Lite Gum or Guar Gum: 0.25%

Yeast: 2.5% (compressed yeast)

Water: 56%

The function of the Guar Gum in this application is to help retain moisture in the par-baked crust which results in a finished crust with more of the characteristics of a crust baked from a raw dough skin. I did all of the initial applications work many years ago.

[Re: Recreating Drive-In Pizza](#)**877**

Craig;

Even though the water is bound by the starch it is still free water and as such it is included in with the dough absorption in the same manner as the water in the eggs would be.

[Re: pour all of the water vs little by little](#)**878**

It should be about the same (80%).

[Re: pour all of the water vs little by little](#)**879**

You can make your own by scalding the liquid milk then add it as part of the dough water remembering that only 88% of the weight of liquid milk is water.

[Re: Yeast donuts recipe?](#)**880**

Alex;

What you are describing is pretty common for a whole-wheat dough. I think your problem might be related to low dough absorption. Your present dough absorption calculates to 68.75% which is low for a whole-wheat pizza dough. Increase the dough absorption to 74% (592-ml) and mix the dough just until it all comes together as a homogeneous dough (it is VERY EASY to over mix a whole-wheat dough). Put the water (18.3C) in the bowl first, then add the honey and all of the dry ingredients including the yeast if it is IDY but be sure to put the IDY on top of the flour (if it is ADY pre-activate it in 50-ml. of warm (37.8C) water for 10-minutes before adding it to the water in the mixing bowl. Mix at low speed until the dough just begins to form then add the oil and mix for 1-minute, then mix the dough at the highest speed possible just until a dough is formed. Take the temperature of the dough, ideally it should be in the 75 to 80F/23.8 to 26.6C) range. Immediately scale and ball the dough and place into lightly oiled fermentation containers, lightly oil the top of each dough ball, leave the lids off of the containers until the internal dough ball temperature reaches 10C then apply the lids BUT make sure you have some form of a vent hole in the lids to bleed of any gas and prevent pressure build-up that might pop the lids off. Cold ferment for NOT more than 24-hours, remove from the fridge and allow to warm AT room temperature until the internal dough ball temperature reaches 10C then turn the dough out of the container(s) onto a flour dusted surface and begin opening the dough into skins by your preferred method. As soon as the pizza comes out of the oven brush the edge with olive oil or as I like to do, use melted butter.

Let me know how this works for you and be sure to post some pictures.

[Re: Bulk Fermenting vs. Individual Balls](#)**881**

The total dough absorption figures out to about 64% (30% as added water, 16% from the boiled potato and 18% from the whole egg) which is high for a yeast raised donut. I would suggest reducing the water incrementally to about 55% or maybe a little less to see how that works for you. As your dough formula is quite

rich I might also suggest using 100% of the high protein flour rather than the blend that you are presently using.

[Re: pour all of the water vs little by little](#) **882**

Your observations are correct in that a short fermentation time makes your observation more pronounced. A longer fermentation time will allow you to mix the dough better and then achieve the desired extensibility through longer fermentation which will, at the same time, provide a better flavored crust that also has better eating properties.

[Re: pour all of the water vs little by little](#) **883**

For the 65% dough absorption here is how you do it:

460 (flour weight) X 65 (press the "%" key) and read the amount of water in the display window. 299-grams is the answer.

We have discussed the leaching of glutathione from ADY or IDY when put into cold water a number of times here, it never hurts to read it again though.

[Re: Pizza Dough - Fails to Retain Shape during Ferment](#) **884**

I'm in agreement with Yael, plus it is actually a lot easier on the mixer. In actuality, you achieve a much more uniformly mixed dough by method #1 while method #2 results in a much more inconsistent dough which is why you were seeing it as being more extensible due to the inconsistent gluten development.

[Re: pour all of the water vs little by little](#) **885**

Are we talking about machine mixing or hand mixing/kneading?

[Re: pour all of the water vs little by little](#) **886**

I can see several issues with what you are doing that might be contributing in part or whole to the issue.

- 1) 67% absorption is a bit on the high side, I'd recommend going lower, possibly start at 65% and go down in 2% increments from there.
- 2) You are putting IDY into the dough water. For hand mixing you should be hydrating the IDY in about 5X its weight of warm (100F) water before adding it to the colder dough water. What you are presently doing can leach glutathione out of the yeast which will have a softening effect upon the dough.
- 3) Do not place the lid on the container until the internal dough temperature reaches 50F, this is especially important when using a long CF period.
- 4) Are you mixing/kneading the dough until it has a smooth appearance? This is important as the smooth appearance is an indicator of gluten development and it is the gluten that helps to hold the dough ball together.

[Re: Pizza Dough - Fails to Retain Shape during Ferment](#) **887**

Peter;

Absolutely! I'm just saying that when people reference a "yeasty" flavor one has to be sure we are all on the same page flavor wise before attempting to answer the question, I wish I had a dime for each time I've gone off on a tangent discussing a true yeasty flavor only to find out later that what the person was looking for was more of the flavor developed by the yeast aka fermentation flavor. It's like the time I got a question on how to develop a true rye flavor in rye bread. I suggested a pumpernickel rye formula (the equivalent of a whole-wheat but with all rye flour) as you can't get more of a rye flavor than that, as it turned out that didn't work either as it still didn't taste like "rye bread" to the individual. So, what was he looking for in flavor? As it turned out he was looking for the missing "mystery"

ingredient, caraway seed! He was relating the flavor of rye bread to that of caraway seed. He never saw the caraway seed in his rye bread because the brand he was buying used either fine ground caraway seed or caraway seed oil for the flavor and because he was buying his bread from a small local bakery they didn't need to provide an ingredient listing on each loaf which might have given him a clue to its use in the bread. I see the same thing when people are looking for a corn like flavor and keep adding corn flour or corn meal but to no avail, in actuality, all they need to add is masa flour aka maseca (the magic ingredient in corn chips that gives them their unique flavor).

[Re: Yeast Amount](#)**888**

Yeast Raised Donut Formula:

Flour: 100% (strong bread type flour with 12 to 12.8% protein content)

Sugar: 6%

Shortening: 10%

Dextrose/glucose: 1%

Bakery grade non-fat dry milk: 5.75%

Salt: 1.75%

Yeast (compressed): 6.5%

Water: 56% (variable)

Mix to a smooth, well developed consistency with a targeted finished dough temperature of 80F.

Ferment for 1-hour at room temperature.

Cut into smaller manageable size pieces and form into loaf shape, cover with a sheet of plastic and allow to rest for 15 to 20-minutes.

Sheet the dough to about 1/2-inch in thickness and cut with desired shape donut cutter.

Place cut donuts on oiled screens for proofing at 100F/75 to 80% Relative Humidity. Proof times will be about 45-minutes.

Fry donuts at 375 to 385F.

Frying time will be about 45 to 60-seconds per side. For Bismarks submerge the donuts after frying the first side to complete the frying process.

[Re: Yeast donuts recipe](#)**889**

Be careful what you wish for as large bubbles being formed during baking can/will rearrange the toppings and create inconsistencies in the top bake of your pizzas. If you just want to create a more open crumb structure you might look at increasing the dough absorption in 2% increments (the more fluid dough consistency will allow for easier expansion of the dough both prior to and during baking resulting in larger bubbles and a more open crumb structure. An increase in the yeast level might also help too as this will promote greater oven spring characteristics resulting in a more open crumb structure in the finished crust.

[Re: Larger Bubbles Before Cooking](#)**890**

Recommendations for home ovens is one area where I seldom tread as there are others here on this web site who are much better versed on the subject than I am, now when it comes to commercial ovens, that's "a horse of a different color".

[Re: Recommendations for Outdoor wood fired/gas fired brick oven](#)**891**

When answering this question one must always ask: What do you mean by yeasty flavor? All too often when further exploring this question I've found that what they are actually referring to is the flavor of "FERMENTATION" not the flavor/taste of

yeast. The taste of yeast is probably best described as that of old, wet newspapers. The other yeasty flavor commonly referenced is that of bread made from commercially frozen dough (very little fermentation and double the normal yeast level), this is a flavor that some might associate with the bread that their Grandma used to make back when Grandmas made bread from scratch. Not knowing specifically which flavor is being referenced as "yeasty" is an exercise in pure futility.

[Re: Yeast Amount](#)**892**

A Boston Cream Donut is nothing more than what is normally referred to as a custard filled Bismark with chocolate dipped icing on top, much like a Boston Cream Pie except in a donut format.

I'll need to look for the yeast raised donut formula you mentioned.

[Re: Yeast donuts recipe?](#)**893**

Pictures of the dough, dough ball prior to opening as well as the finished crust would all be helpful in this case. It sounds like you might be allowing the dough balls to rest at room temperature too long before opening them into skins. The next time you make dough try opening dough balls at 2, 4, and 6-hours and compare the resulting crumb structure to see in opening them any sooner helps to create a more open, porous crumb structure.

[Re: Larger Bubbles Before Cooking](#)**894**

While a plastic fat can be added right along with the flour in most pizza applications in this case where we have the GDL + soda mixed into the fat it should still be added later in the dough mixing process to help prevent any of the fat from being scrubbed off of the chemical leavening contained in the plastic fat. With the bake to rise concept you really want to limit the amount of fermentation that the dough receives. A little fermentation is OK but a lot of fermentation only leads to a sub quality finished pizza. The steps you have outlined for freezing a bake to rise pizza are valid and should work well as far as the dough is concerned but freezing vegetable toppings is never a good idea if you want to have a decent finished pizza that isn't wet and soggy. This can be done commercially using either moisture controlled vegetable toppings or employing either mechanical or cryogenic blast freezing techniques. The Nestle DiGiorno/Delicio/Giordano's brand frozen bake to rise pizzas employ both moisture controlled vegetable toppings as well as blast freezing and highly specialized packaging to achieve the level of quality they have. Bake to rise pizza is not a new invention, it has been around for a VERY LONG TIME, over 70-years! When I was a small child my first introduction to pizza was the Chef Boyardee pizza kit. We have discussed this previously here if you wish to read more about it. Papa Murphy's take and bake pizza chain is a well known user of this concept (their stores don't even have an oven). It was mentioned that you could make these pizzas on a par-baked crust, this is not correct as a par-baked crust will not rise during the baking process, instead it will be just another form of a pretty standard frozen pizza that one might pick up at the local supermarket. The bake to rise concept pizzas must be made using a raw dough to allow it to rise during baking. I totally agree that it would be a lot easier to make the school's pizzas using a par-baked crust, then all they would need to do is to bake the pizzas long enough to fully cook the toppings and warm the crust, you will get a crispier finished pizza and for the most part, a better tasting finished pizza too as you can use a more standard dough formula utilizing more fermentation to build in flavor and you won't need to contend with any off flavors resulting from the CL (chemical leavening) system used in the bake to rise dough formulation.

[Re: Rising crust pizza - SALP alternative?](#)895

Fermentation time v/s yeast quantity, that is the question.

Adding more yeast to a dough is not a substitute for fermentation time because just adding more yeast will provide more leavening power but it will not provide the necessary time needed for the byproducts of fermentation (acids, alcohol, carbon dioxide) to begin breaking down the flour proteins. Additionally, there are enzymes present (amylase and protease) which hydrolyze starch and proteins during the fermentation process which further conditions the dough making it easier to work with. All of this degrading of starch and protein also help to contribute to the flavor profile of the finished (baked) crust as well as adding to the overall digestibility of the crust. The key is "time", these reactions all require time to take place they do happen to a lesser extent with short fermentation times and higher yeast levels but not to the same extent as is achieved with a lower yeast amount and a longer fermentation time.

[Re: More yeast vs more fermentation time?](#)896

There are a couple of problems associated with targeting a finished dough temperature as low as something in the 50 to 55F range;

- 1) Cold flour does not absorb water as readily as warm flour so a longer mixing time will be required, a longer mixing time = more bowl friction = more heat generation = increase in finished dough temperature, it's kind of a Catch 22.
- 2) The dough itself is very stiff at low temperatures, as the dough temperature drops below 65F the dough quickly becomes progressively stiffer/firmer/harder, whatever you want to call it. This by itself results in greater warming of the dough through increased bowl friction.
- 3) From a commercial standpoint about the lowest temperature that can be realistically achieved is 60 to 65F (60F is really pushing the envelope), and to accomplish that both refrigerated water and direct expansion refrigeration of the mixing bowl are required which means that a horizontal bar type mixer will be needed to mix the dough so we are talking about commissary type operations here as opposed to home or pizzeria.
- 4) Keep in mind that you would need to have the dough at 50 to 55F not just coming off of the mixer, but still at that temperature after scaling, balling (rounding) and boxing. The lowest finished dough temperature that I've encountered in the production of pizza dough was 65 to 67F and that was in a large box store commissary, even at that, with a mixing room temperature of 55F the actual dough temperature going into the cooler was closer to 75F than 67F. Aside from these obstacles, it would be nice if we could bring the dough off of the mixer at a temperature where we could get it into the cooler within the 50 to 55F range as that would eliminate the need to cross-stack and down-stack BUT at the same time it would impact our dough management procedure as the amount of fermentation that the dough receives during the cross-stack period plays an integral part in our dough management procedure by allowing for the development of acids and allowing enzymes to do their job as well as changing dough density which further impacts the way the dough continues to ferment in the cooler especially when considering the impact of heat of metabolism during the residence time in the cooler.
As a side note, frozen dough is typically made using a dough with a targeted finished dough temperature of 65 to 70F (highly specialized horizontal bar type mixers are required for this task), the dough is then immediately scaled and rounded, slightly flattened, and it then immediately proceeds to the blast freezer where it is blast frozen to a core temperature of 15F +/- 2F, it is then packaged and

held in a holding freezer for 24-hours at -10F prior to shipment/distribution. The idea here is to render the dough "stable" by getting it frozen before any significant fermentation begins. This is the reason why bread made from frozen dough has little or no fermentation flavor.

[Re: Final Dough Temperature](#)**897**

Your pizzas look GREAT! :drool:

[Re: Trying for consistency lower TF](#) **898**

The proportions of GDL to soda are 2.2-parts GDL to 1 part soda. The amount to use of the GDL + soda blend is 3% of the total flour weight. Do NOT use any oil in the dough formula, instead use a plastic fat/shortening (DO NOT use butter or margarine as they contain water). Put the fat into a small bowl and add the GDL +soda blend and using a fork or spatula mix the two together until the GDL +soda is THOROUGHLY incorporated into the fat, then you can add the fat to the dough formula and begin mixing the dough.

Adjust the amount of yeast to 0.25% compressed yeast or its equivalent of ADY or IDY. Target a finished dough temperature of 65F. Immediately after mixing scale and ball the dough, set aside to ferment at room temperature just long enough for the dough to be able to be easily opened (about 2-hours?), open the dough into a skin, place in an ovenable pan or on a piece of oven parchment paper and place on a pizza circle and store in the cooler for at least 1-hour, remove from the cooler and lightly oil the top of the skin, dress to the order, wrap in stretch wrap and place back in the fridge for at least 3-hours prior to sale/use.

If these will be baked in a home oven you will want to include 7% bakery grade sweet dairy whey powder or 5% sugar in the dough formula.

I've got formulas and procedures posted in the RECIPE BANK at <www.pmq.com>
[Re: Rising crust pizza - SALP alternative?](#)**899**

The only other real option which you have is GDL (glucano delta lactone).

[Re: Rising crust pizza - SALP alternative?](#)**900**

Yes you do, but remember that the scheduling of those fermentation periods is just as important as the total fermentation time, for example, if we are going to give our dough 24-hours total fermentation time there will be a huge difference in how the dough handles if we were to ball the dough immediately after mixing and then give it 24-hours of undisturbed fermentation as opposed to fermenting the dough for 23-hours and then balling it and trying to open it into a skin only an hour later. This is one reason why I personally like to scale and ball the dough immediately or soon after mixing and then allow it to ferment in ball form for the bulk of the fermentation time (whatever that might be), when managing the dough in this manner you are almost assured of a dough ball that will be very relaxed and open easily.

[Re: Fermentation time counting question](#)**901**

If you cannot find SALP (sodium aluminum phosphate) try looking for CAPP (calcium acid pyrophosphate) it has a neutralizing value (N.V.) of 67 so the CAPP will equal 67% of the amount of baking soda used. If you are not using a commercially encapsulated product such as Wrise use a plastic fat instead of oil in the dough formula and blend the CAPP and the soda into the plastic fat.

[Re: Rising crust pizza - SALP alternative?](#)**902**

You should lightly oil the dough ball and leave it uncovered for at least 2-hours,

then cover it for the duration of the cold fermentation time.

[Re: Trying for consistency lower TF](#) **903**

A dough loading of 0.088 ounces per square inch is about average for a N.Y. style pizza so your 0.09 target is pretty close but your IDY level of 1% is much higher than what is normally used, in fact it's about 3X higher than normal which might be giving you a thicker than normal finished crust. My suggestion would be to drop the IDY down to 0.375% and see if the finished crust thickness is more to your liking.

[Re: Trying for consistency lower TF](#) **904**

Jamie;

Have you considered the possibility that the problem might be with the oven? Not knowing anything about your oven I can't say, but if the oven has a very high crown that could account for the problem. Most operators with that problem address it by baking the pizza until the bottom is done (the way a pizza should be baked) and then lifting the pizza up into the crown of the oven to finish off the top. I've done this many times myself and it works well.

[Re: Pizza base burns underneath later in the day at restaurant](#) **905**

Pete;

Pretty much all of it is correct. Getting a thorough bake is critical for achieving a more tender eating crust on the rolls. More yeast will help with oven spring for a better bake as will more fermentation of the dough, this is why I was a bit concerned over the rolls going straight from the fridge into the oven as a refrigerated roll of any kind is more difficult to bake than a roll at room temperature. Depending upon the dough formulation a little fat in the dough formula can also be beneficial as it promotes oven spring, heat transfer and produces a more tender eating characteristic.

[Re: Dough to hard to chew](#) **906**

You can use any type that is readily available to you. The type of pizza being made does not dictate the type of yeast used but many like to use IDY due to its uniformity, ease of use, and long shelf life.

[Re: Yeast types and uses](#) **907**

Jsaras;

Attend seminars directed at new operators and when on the show floor get as much information from vendors as possible (even "stuff" you don't think you will ever need) then when you get back home organize it in several 3-ring folders for use as a quick reference guide in the future, you'll be glad you did! Also visit with ALL of the different oven companies as well as the dough mixer and pan suppliers their information will be invaluable if you decide to "drop the hammer".

[Re: Pizza Expo 2020](#) **908**

Please show us your dough formula and complete dough management procedure to include times and temperatures as well as information on the flour you are using as this will help us to better identify what's causing the problem.

[Re: Bulk Fermenting vs. Individual Balls](#) **909**

Everybody know you're not supposed to eat dough! :-D :-D :-D

Getting to you point, a couple of things come to mind;

1) Five hours fermentation probably wasn't enough fermentation time for your

dough made by your specific dough formula, overnight would have been better. 2) It looks like you took the dough straight from the fridge to the oven which further compounded the issue as this would reduce the oven spring characteristics of the dough resulting in poorer bake out which in turn results in a tougher, chewier finished crust or roll in your case. You would most likely have been better off by just leaving the made up rolls rest at room temperature for that hour rather than putting them in the fridge.

[**Re: Dough to hard to chew 910**](#)

Whey powder isn't the issue, it's the heat treatment of the whey that's the issue. They are using what is referred to as high heat treatment aka bakery grade whey powder that has already been heat treated to denature the specific whey proteins responsible for creating the softening of the dough. Think of it like you would fresh eggs, all fresh eggs are considered to be dangerous to consume without proper heat treatment (cooking), but after heat treatment they are fine to eat. ;D

[**Re: Replacing water and powdered milk with whole milk?911**](#)

I would consider 25C water to be cool, not warm (32C+ would be considered "warm") but with that said, 25C is a good water temperature to use when making your dough, however, I would encourage you to put the ADY into 4 to 5-times its weight of warm (37C) water to hydrate and activate it, then just add it right to the dough water in the mixing bowl. After adding the yeast suspension go ahead and add all of the remaining ingredients and incorporate by hand until a dough begins to form (about 5-minutes), turn the dough out of the bowl and scrape the bowl clean, lightly oil the bowl, knead the dough for just a couple of minutes and form it into a ball and place back into the mixing bowl or other suitably sized container (be sure it's lightly oiled), allow to ferment for about 2-hours (this will allow for some biochemical gluten development to take place), turn the dough out of the bowl and knead until the dough begins to take on a smooth appearance (about 5-minutes?), place dough back into the lightly oiled container and allow to ferment for 30-minutes, turn the dough out of the container and scale/divide into desired weight pieces, form each piece into a ball, lightly oil each dough ball and place into individual plastic bread type bags, twist the open end into a pony tail to close and tuck it under the dough ball as you place it into the fridge to cold ferment for 48-hours. To use the dough, remove from the fridge about 2-hours prior to use time, roll the bag down around the dough ball and invert over a floured surface allowing the dough ball to fall from the bag, flour both sides of the dough ball and open into a skin by your preferred manner, the skin is now ready for immediate use.

[**Re: Problems with NP dough in 70% hydration912**](#)

I've not seen corn starch added to the dough formulation but it is commonly used in icings and glazes and it is an integral part of powdered sugar.

[**Re: Dunkin' Donuts Yeasted Donuts copycat913**](#)

Cultured quartz, offers both beauty and durability with little to no maintenance and it's widely available even at home centers.

[**Re: Remodeling kitchen...Best surface?914**](#)

RedSauce;
My feelings exactly.

[**Re: SAF High Power IDY915**](#)

I would tend to agree with that. That is not the same as putting the ADY directly

into a pizza dough with a more typical absorption of 62 to 66%.

[Re: Problems with NP dough in 70% hydration](#)**916**

When ADY is not correctly hydrated glutathione can/will be leached out of it resulting in some inconsistencies in your dough both due to the reducing effect of the glutathione and also due to the fact that yeast cells from which glutathione has been removed from will not ferment.

You might not readily see this but it is happening.

[Re: Problems with NP dough in 70% hydration](#)**917**

Gus;

Putting oil in the dough will help to allow the dough to rise better and it will certainly tenderize the crumb so the pizza is Less, not more chewy. Because oil repels water it also helps to prevent the development of a gum line in the crust during baking (putting oil on the skin prior to applying the sauce will serve the same purpose). Your procedure really isn't all that complex so I really wouldn't worry about it. The one thing to do next time you make pizza is to use colder water as this will help to lower the finished dough temperature.

[Re: Oil in dough](#)**918**

In addition to what Yael said, I'd also suggest hydrating/activating the ADY in a small amount of warm (38C) water for about 10-minutes prior to adding it to the dough water in the mixing bowl.

[Re: Problems with NP dough in 70% hydration](#)**919**

It all depends upon how much fermentation you want to achieve during the CF period. Remember that the fermentation rate will dramatically slow at temperatures below 45F and almost stop at temperatures of 40F and lower, so at 42F there won't be very much fermentation taking place. At 50 to 55F internal dough temperature there will be a measured amount of fermentation taking place which is suitable for dough that will be subjected to up to 72-hours CF but yet it will still be "usable" at the 24-hour mark if necessary. Dough which is allowed to cool to a lower temperature will require more time to fully ferment so if you are planning to hold the dough for 5 to 7-days or more cooling it to a lower temperature is the right thing to do but keep in mind that the dough will be under fermented at the other end of the spectrum (24 to 48-hours). There are some "00" flours which have a very short fermentation tolerance and allowing these doughs to cool to a lower temperature would be an effective way to better manage dough made with these types of flours. As for working with reach in coolers we have found that it is desirable to reduce the finished dough temperature by at least 5F when using a reach in cooler as opposed to a walk in cooler due to the lower efficiency of the reach in when loading it with dough.

I hope this has answered your question.

[Re: Cooling the dough balls down to an internal temperature of 50 to 55F](#)**920**

Have you "poked" around at other independently operated stores to see if you can find out where they source their materials from? I would have guessed that there would be some type of distributor in Anchorage that you could order from or special order from, if not maybe a distributor on Washington or Oregon might be able to get things to you a bit cheaper?

[Re: Supplies in Alaska](#)**921**

No, it's because when a large wholesale account receives their flour it comes in a

tank car (road or rail) and it was milled immediately before shipment (usually just hours or a day at most after milling) so it is easy to have a Farinogram report specific to that particular lot of flour. With bagged flour the routing is different as the flour goes from the mill in bags to a mill storage area, then its shipped to a distributor and then sometimes another distributor like an ingredient vendor this makes it difficult to match the bagged flour to a Farinogram report, and add to that, unless you specify from your vendor not to mix lot numbers on an order, you may find that your flour shipment consists of two or more different mill lots. Due to laws regarding trace ability it probably wouldn't be too difficult for the mills to have a computerized system where you would enter your lot number (shown on each bag) and it would give you a page showing the Farinogram report. Then there is the issue of explaining just what it is and how to use it as well as how to develop a Farinogram factor for each of your doughs. That sounds like a lot of work to me for any company that is highly competitive and trying desperately to keep their costs down. A possible solution would be to charge an annual fee to access such information, I don't know how many operators would avail themselves of such a program though, but it's a thought.

[Re: All Trumps Unbromated/Unbleached - Inconsistencies?922](#)

In our pizza classes I used to ask my students if they could tell me what the difference between flour and hockey pucks was.

Answer: Hockey pucks are consistent and always the same. Flour isn't. This is why large commercial bakeries have a FARINOGRAM REPORT ON EACH AND EVERY LOT OF FLOUR THEY RECEIVE. The Farinograph report gives vital information on flour absorption, mixing time and overall strength of the flour allowing them to make the necessary adjustments right up front without any surprises. Most of the time we see the most significant changes in flour during the period which is referred to as new crop change-over, this is when the new crop is just coming into the mills, for spring wheat based flours this is usually mid-August to early September. For winter wheat based flours this is usually mid July to early August.

[Re: All Trumps Unbromated/Unbleached - Inconsistencies?923](#)

You might find some advantage to adding a very small amount of malt to the biga if you are fermenting the biga for several hours. If you are baking your pizzas at or above 750 to 800F I'd suggest a non-diastatic malt but if you are baking at a lower temperature I'd use a diastatic malt.

[Re: Why and when is it recommended to use malt in the dough?924](#)

My own personal peels are all wood peels, they're hard to beat for any kind of dough and they dramatically reduce the incidence of the dough sticking to the peel. I use aluminum peels as my oven peels only.

[Re: Pizza peel choices925](#)

Spot-on!

My suggestion would be to ball it immediately after mixing (when you scale it) and then lightly oil the containers, drop the dough ball into the container, lightly oil the top of the dough ball, leave the top of the container off when you place it into the fridge until the internal dough ball temperature reaches 55F/12.8C, then apply the lid for the duration of the CF period. When ready to use the dough, remove from fridge and allow to temper to 50F/10C, then begin opening the dough ball(s) into skins. You will want to experiment with the final temperature (50F/10C) as some find it easier to open into skins at a slightly higher temperature. You probably won't

want to go more than 65F/18.3C though.

[Re: Having issues stretching dough? Seems to stretch unevenly.](#) **926**

Getting back to a very basic question: Is your flour malted in any way?

[Re: Why and when is it recommended to use malt in the dough?](#) **927**

If you're not scaling and balling before the CF period, when are you scaling and balling? Also, how much fermentation is the dough getting in ball form between balling and opening? Am I missing something in your procedure?

[Re: Having issues stretching dough? Seems to stretch unevenly.](#) **928**

Yeast, a living organism needs to feed and it feeds off of sugar that is both added to the dough as an ingredient (the exception being lactose which is not metabolized by the type of yeast we use) and also the enzymatic conversion of starch into sugar by the enzyme amylase which is both present with the yeast and also added to the flour by the miller as sprouted barley flour (malted flour). As yeast feeds it produces carbon dioxide, acids (acetic, lactic, and propionic) and alcohol. What John is referencing as "Zing" is a slight acidity formed when the carbon dioxide gas is dissolved in the water from the sauce creating a mild acid (carbonic acid). He is correct in the formation of this acid but I would question if it is a significant factor in the flavor of a pizza since the other three acids formed are significantly stronger and are recognized for their contribution to the flavor profile of a pizza. The slight tartness, regardless of how it is formed or what acid is responsible, is an important aspect of our sensory response to a food in that it makes us salivate and we unconsciously associate salivation with something that tastes good to us.

[Re: papa johns pizza ZING](#) **929**

There is a very good reason why large, commercial bread ovens (not artisan, that a whole different story) have an air circulating device that's called a "colorator" installed in them, they are installed in the oven at a point late in the baking stage where they serve to provide precise control of crust color after the loaves have been baked. Like I said, rotating rack ovens are much like a home convection oven but without the airflow they are plagued by one major issue, that is heat stratification so the products at the top of the rack bake at a different rate than that at the bottom of the rack until the airflow is turned back on again. To get around this many ovens now pulse the airflow fans for a set period of time at the beginning of the bake cycle. About the best I can say for it is that "it works".

[Re: convection and undercooked dough - lou's semolina](#) **930**

True, but they lack the capacity needed by many pizzerias.

[Re: convection and undercooked dough - lou's semolina](#) **931**

I agree with the comments from Bob's Red Mill. But remember that while the baking trays rotate through the oven cavity in a reel oven they are not considered to be convection ovens by any sense. Convection ovens are characterized by a much greater and focused airflow over and around the product. This should not be confused with air impingement baking which is totally different in that it employs VERY high speed airflow which is VERY highly focused on the product during baking (the technology of baking is very different from convection baking). Reel ovens are the mainstay of the retail baking industry where they serve to bake everything from pies, cookies, pastries, as well as all types of breads and rolls. Rotating rack ovens are a form of convection oven which is utilized in the baking industry and much like many home ovens, they have a feature which allows for

shutting off the convection fans for a portion of the baking cycle in order to prevent peaking of layer cakes and poor crust development on loaf breads.

By the way, Chicago pizzas are given a long bake time to ensure the raw sausage (what is Chicago style pizza without the use of raw sausage?) is fully cooked. My favorite Chicago pizza places are Nancy's, Uno, Due, Gino's and Beggars.

[Re: convection and undercooked dough - lou's semolina](#) 932

Pete;

There is a huge difference in the way a deck oven bakes and the way a reel oven bakes. Thin crust Chicago pizzas are typically baked in a reel oven at 500 to 550F for just shy of 30-minutes while the deep dish pizzas take a bit longer at nearly 45-minutes. This is why the reel oven are so popular in Chicago, they have a huge capacity when long baking times are the order of the day. Deck ovens have their burner located immediately below the deck in order to maintain deck temperature and recover temperature quickly while reel ovens have a single ribbon burner across the bottom of the oven and the shelves (decks) just rotate through the heated air. There is also a big difference in crown height of the two ovens also, deck ovens have a relatively low crown height measured in just a few inches while a reel oven really doesn't have a crown. Middleby-Marshall reel oven are the most common reel ovens encountered in Chicago. Cobblestone Oven company is a major supplier of these ovens in Chicago, they don't make them and they are not a distributor, they refurbish existing ovens and resell them. When maintained they will last just about forever.

Places making an authentic Chicago style pizza will often use a reel type oven, occasionally they will use a Middleby-Marshall but more commonly I see the smaller reel ovens made by Fish and Reed Oven Company being used unless they are a high volume shop.

[Re: convection and undercooked dough - lou's semolina](#) 933

Remember, NEVER, EVER soak any seasoned pan in water! The seasoning will begin peeling off like a bad sunburn then you'll need to strip all of the remaining seasoning off of the pan(s) and start all over again.

We have previously had some discussion on how to clean seasoned pans if you want to look back through the archives.

[Re: Aluminum pans for Chicago deep dish](#) 934

A spiral mixer operating at 80% of capacity is a "walk in the park" for that design of mixer. They are not nearly as load sensitive as planetary mixers are, and one thing that's a sure bet is that a spiral mixer will outlast a planetary mixer any day of the week and with a lot fewer repairs during its life span.

[Re: Spiral Mixer \(commercial\) recommendations and general feedback](#) 935

Pete;

What temperature are you baking it in your reel oven? What shelf material do you have (steel, transite, or open grid?)

[Re: convection and undercooked dough - lou's semolina](#) 936

Also check out your state SBA (Small Business Assn.) to see what kind of assistance they can provide. We used to have a program called KVAC (Kansas Value Added Center), it was a state funded association operated through Kansas State University comprised of volunteer and retired business people whose sole purpose was to assist new start up businesses in the state of Kansas. All at no charge to the client. We were paid a token stipend for our time through the KVAC program. I

don't know if New York state has anything like this but from all the hype I hear from N.Y. about a "business friendly" environment I would think that they would have something similar in place.

[Re: Business planning for new shop](#)937

I'm betting that the best research team at M.I.T. could not come up with a poorer shape for freezing than a round ball shape (think dough ball). Just remove the dough balls from the box and flatten to about 1-inch, or so in thickness, then place in the freezer. They will freeze much more thoroughly and faster than they would if left in ball shape and you will have markedly improved your chance at success in making pizzas using the frozen dough at the same time.

[Re: Calling all Dough Savers](#)938

Just to confirm, you want to make a New York style pizza that has a crispy crust as opposed to a more typical fold able crust common to N.Y. pizzas. It sounds like you want to make a New Haven style pizza which I've often described as a New York style pizza but with a crispy crust.

Here is a good dough formula to start with;

Flour: 100%(strong bread flour)

Salt: 1.75%

Sugar: 2%

Oil: 2%

IDY: 0.375%

Water: 64% (variable)

Mix dough using delayed oil addition mixing method, and mix just to a smooth dough consistency.

Targeted finished dough temperature: 75 to 80F

Basic Procedure:

Mix

Scale and ball

Box and oil top of dough balls.

Cross-stack in cooler until internal dough ball temperature reaches 55F.

Down-stack

Allow to ferment for a minimum of 24-hours, best at 48 to 72-hours.

Open dough balls into skins by hand.

Dress and bake at 500F.

[Re: ny style dough that cracks when folding](#)939

While Kansas USED to be known as "The Wheat State" about 6-years ago corn surpassed wheat as the main agricultural crop in Kansas.

To keep on top of what is actually happening to wheat prices you have to look at the world picture and take into what the wheat crop in Brazil, Argentina, Canada, Australia, China and Russia are doing. Generally it's not a big issue if one of those countries falls behind as the other countries will export wheat to make up the difference but if several or all of them face issues with their wheat crop (like we saw about 12-years ago where ALL of them faced severe issues) it will go to a whole new playing field where wheat might not even be available and when it is it will be expensive and flour prices will spike through the roof as they did back then. If we ever find ourselves in that spot again (we probably will) watch the world wheat carryover, there are the world wheat reserves, when things were really bleak we were down to less than 3-days! Think of it like this, you are out of a job

and can't find employment and you are now tapping into your 401K (the wheat reserves), when it's gone you are up that proverbial creek without a paddle.

[Re: U.S.D.A. forecasts the smallest all-wheat area on record](#) **940**

Dough absorption is the amount of water added to the dough, it is expressed in percent of the total flour weight used to make the dough. For example, if we made a dough with 700-grams of flour and it required 400-grams of water to give the desired handling and finished crust characteristics the dough absorption in this case would be 400 divided by 700 X 100 or 57.14% (we would round that off to 57%). All of the other dough ingredients are also expressed in this very same manner.

If you have a dough formula (dough formulas are based on weight measures (grams, kilograms, ounces, pounds, etc.) while recipes are based on volumetric portions (teaspoons, tablespoons, cups, buckets, etc.) that is given in percentages and you want to find the weight for those percentages it's very easy to do:

- 1) Decide how much flour you want to use by weight measure.
- 2) Using your calculator, enter the flour weight then press "X" followed by the ingredient percent that you want the weight for and read the ingredient weight in the display. The ingredient weight will always be in the same weight measures that the flour is shown in.
- 3) Flour is always shown as 100%.

I used to tell my students that it is just like calculating the amount of a tip where the flour weight is the cost of the meal and the ingredient percent is the percent of the tip that you want to leave.

[Re: Neapolitan Pizza - Puffy Airy Crust \(Canotto Style\)](#) **941**

BBE;

65% RH (relative humidity?) You most likely mean dough absorption (65% water based on the total flour weight). A finished dough temperature in the 70 to 75F range is recommended when the dough will be mixed entirely by hand as the colder dough temperature makes for easier dough kneading. When machine mixing is used we typically recommend a finished dough temperature between 75 and 80F unless there is poor refrigeration and in that case it's back to the 70 to 75F recommendation. Targeting a higher finished dough temperature just makes the dough more sensitive to slight differences in finished dough temperature as well as room temperature. For example, at 72F the dough will show little effect of missing the targeted temperature range by 2 or 3F (like 77 or 78F) but that same dough at 80F and getting a finished dough temperature of 82 or 83F the dough will show greater effect in the form of faster fermentation as well as being more difficult to cool after being placed into the fridge. The reason for waiting for the dough to drop in temperature to 55F before covering it in the fridge is to reduce the propensity of a warm dough to sweat in the lidded container but more importantly to ensure that it has cooled to a point where it can be further cooled even though the container is lidded at a constant and predictable rate. Remember, just putting the dough into the fridge doesn't stop fermentation, the dough MUST be cooled to a temperature below 40F to retard fermentation, if not the dough will over ferment or blow, and to add insult to injury, the dough is always in the process of warming up due to the heat of metabolism resulting from the fermentation process. This is why I've always said that you cannot have effective dough management without temperature control.

[Re: Finished dough temperature range](#) **942**

Peter;

It doesn't make sense to me either. In many cases where high salt levels are used it is the step taken to control the fermentation rate that has resulted from improper dough management (failure to cross-stack or lidding fermentation containers too soon) or just lack of dough temperature control. Once these are properly addressed the high salt levels are no longer necessary and in my opinion, desirable as there is plenty of salt coming from everything that is put on top of the dough.

Marolla1;

The way to measure dough temperature is by use of a dial aka stem type thermometer.

[Re: Why is it happening?943](#)

You really can't, but I'll give you an example, years ago we R.E. the Papa Murphy's crust and found that the sweetness perceived in the finished crust (not the dough) was due to 5% sugar. So if you back it down to 2% to see if that gets the color back on track you can then begin incrementally increasing the sugar to get some sweetness in the finished crust, and if it's sweetness that you are after I suggest limiting your total fermentation time to not more than 24-hours CF, this is because fermentation = acid formation and acid = tartness, tart is just the opposite of sweetness. From an ingredient standpoint you might consider replacing any fat in the dough formula with ghee as this will contribute to a perception of sweetness in the finished crust.

[Re: Too much char?944](#)

Fyre;

Do you realize that you are using 7.5% sugar in your dough formula? A more typical level would be 1.5 to 2%. At this sugar level you should get a more even, uniform browning by baking on either a screen or directly on the oven deck. Make this one change and let us know how it works for you. Include pictures if possible.

[Re: Too much char?945](#)

Brian;

Just be sure to season your new tin-plate pans well prior to their first use or they won't bake any differently than your aluminum pans, and once you have them well seasoned NEVER soak them in water for any reason. If you do, the seasoning will begin to peel off like a bad sunburn and you will need to strip all of the seasoning off of the pan and start all over again. Instead, to clean the pans just wipe out with a clean towel or if you feel absolutely compelled to wash the pans grasp pan in one hand, dip in soapy water, LIGHTLY scrub with a soft plastic bristle brush, rinse in clear water, wipe dry (NOTE: At no time did I say to release your hold on the pan), now place the pan into a warm oven to force dry for about 15-minutes, now you can put the pan away. If you don't follow these basic rules for a seasoned pan these infamous words will haunt you: "I told you so". :D

Welcome to the site!

I'm an ex south sider (Tinley Park).

[Re: Hello From Chicago!946](#)

I would advise not using more than 25% combined spelt and semolina flour to start with, then you can begin to incrementally increase the spelt-semolina flour blend to whatever your specific flour will accept. You will also want to determine the correct absorption value for the spelt-semolina blend that you use. If you search back through the archives we have had a lot of discussion on whole-wheat and multi-grain blends, in this discussion I explained in detail how to find the absorption of

these "composit" flour blends. I would also highly recommend that you put the composit flour blend in an autolyze for a minimum of 1-hour to allow for complete hydration prior to actually mixing the dough.

[Re: Flours for Roman-style pizza dough](#)**947**

When using IDY and hand mixing the dough it is always a good idea to suspend the IDY in a small portion of warm (95F/35C) water before adding it to the dough. You should be targeting a finished dough temperature in the 70 to 75F range, and you should not be lidding the containers right away, instead, very lightly oil the top of the dough after it's in the container, then allow the dough to cool in the fridge until the internal dough ball temperature is 55F/12.7C, then apply the lid for the duration of the cold fermentation period.

Unless you're really big into physical fitness and want arms like the village blacksmith all of that kneading really isn't necessary. Let biochemical gluten development do the work for you. Just knead the dough until it begins to take on a smooth appearance, then scale, ball and place into the fermentation containers.

[Re: Why is it happening](#)**948**

I'm confused, you use flour or semolina flour on the peel to help with peeling the skins but yet you say you are baking for at least one minute on screens?

If you can share your dough formula as well as dough management procedure it would be a big help.

[Re: Too much char?](#)**949**

I agree, I also think the dough is too thin, When making rolled items I always like to use a rolling pin or pastry pin to open the dough as this gives me a more uniform dough thickness than opening by hand. A uniform dough thickness is important as it helps to eliminate blow-outs. I also like to make several French cuts across the top of each roll to allow steam to escape and to allow for controlled expansion during baking. In some cases it also helps to spray the rolls with water immediately before placing in the oven, this allows the dough to expand a little during oven spring which reduces the chance for a blow-out.

[Re: roni roll bursting open](#)**950**

Another option for the home (what I use) is a wood (maple) top. They're very reasonable priced and available from most home centers like Menard's. For a commercial application cultured quarts is also a good option as it doesn't stain or discolor and is nearly bullet proof in all other ways and you can get it in just about any color you want.

[Re: Prep table](#)**951**

Here is a quick summary of my suggestions;

- 1) Two speeds are better than a single speed.
- 2) Reverse rotation is a nice feature to have.
- 3) A removable bowl can make life a lot easier in some shops.
- 4) A drain plug in the bowl makes cleaning a LOT EASIER.
- 5) Spiral mixers will effectively mix a dough as small as 25% of stated bowl capacity or as large as 115% of stated bowl capacity so size your mixer so your dough size is close to being in the middle of this bracket.

Note: To clean a spiral mixer, put a couple gallons of HOT water in the mixer, cover bowl with a plastic sheet, allow to steam for 20 to 30-minutes, scrub with a long handle plastic pot brush, pull the drain plug and drain while rinsing with clear water, sanitize, reinstall drain plug. Without that drain plug you will need to bail

the water out of the bowl (now you understand why the drain plug is important).
[Re: Spiral Mixer \(commercial\) recommendations and general feedback](#)**952**

Unless the flour is malted or you have added diastatic malt to the dough/biga formula the use of a biga will actually result in a lighter crust color. This is due to the fact that a biga is fermented and one of the byproducts of fermentation is acid (acetic, lactic and propionic), these acids lower the pH of the dough which inhibits its ability to develop color during the baking process. This is why sourdough breads are always lighter in color. If diastatic malt or amylase enzyme is present the starch portion of the flour can be hydrolyzed into sugars (malt or dextrose) which provide a nutrient for the yeast as well as helping to develop crust color during baking.

[Re: Why and when is it recommended to use malt in the dough?](#)**953**

Also, what was the finished (mixed) temperature of the dough? How did you put the dough balls into the fridge (type of container, was it lidded or not?)

[Re: Why is it happening](#)**954**

Have you looked at the not too far distant archives for the discussion we have had on spiral mixers?

[Re: Spiral Mixer \(commercial\) recommendations and general feedback](#)**955**

A couple of things to comment on;

1) Your dough absorption is 65% which would normally be pretty typical but as you are using VWG at 5.5% (VWG has an absorption of approximately 175% so 5.5% VWG would be responsible for 9.6% of that 65% absorption) so the overall absorption of 65% may seem OK but in reality it might be too low? I suggest increasing the dough absorption in 2% increments to see if the dough becomes any easier to open.

2) Your dough ball count in the box is too high, reduce the dough ball count per box by 50%.

[Re: Dough Management Problem](#)**956**

To better answer your question I really need to see a picture of the burst toll.

[Re: roni roll bursting open](#)**957**

I'm of the same opinion as TXCraig1, the "C" hook aka dough hook doesn't work in any size mixer unless the bowl is at near maximum dough capacity which probably explains why we used to see sooooo many used Hobarts totally worn out. The reverse spiral dough arm was first made available back in the late 60's (AIB did prototype dough testing with it at the time), thankfully, the reverse spiral dough arm is now standard equipment with all new Hobart mixers (at least the large ones that I deal with). When Hobart made their own motors it was a very different "ball game", but around 1975 they were forced to contract all of their motors, what they got were gutless wonders. When AIB moved from Chicago, IL to Manhattan, KS in 1977 I had several of the old Hobart A-120 (12-quart) mixers as well as an A-200 (20-quart) mixer. Hobart agreed to exchange all of our old mixers for new models but I kept my old mixers as they were in excellent condition. After setting up shop in Manhattan we discovered the shortfalls of those new mixers. Remember, I kept my old ones so it didn't impact me or my lab at all but others were in for a huge surprise, the new mixers would stall with the same dough size that the old ones were mixing on a daily basis, and the speed would vary as the dough developed (not good for research) while my old ones just kept plugging along just fine. It

really wasn't until they came out with the Legacy line that they seemed to get things under control.

[Re: Spiral Dough Hook for KitchenAid Artisan?958](#)

Ya gotta season those bright colored aluminum pans unless you like light colored crusts. We have discussed this a number of times here as well as how to maintain those seasoned pans.

[Re: Aluminum pans for Chicago deep dish959](#)

Let's go by the old adage of "first things first" and if absorption doesn't help then we can dig into dough management.

[Re: Neapolitan Pizza - Puffy Airy Crust \(Canotto Style\)960](#)

Start increasing the dough absorption, first by 5% then after that in 2% increments, that should help to open the crumb structure. With the crumb structure more open you may find that the crust is developing too much color, address that by eliminating the sugar from your dough formula.

[Re: Neapolitan Pizza - Puffy Airy Crust \(Canotto Style\)961](#)

Alex;

Try it, see if it works.

Something to ponder; Maybe the cheese you are using isn't well suited to high baking temperatures? Maybe try a different cheese too.

[Re: Correct Pizza Oven Temperature962](#)

Pictures of your pizza would have helped immensely, but since we don't have that to go on I'm going to take a "SWAG" and say that you will need to increase the dough absorption to at least 65% or more, and bake at a higher temperature, not knowing anything about how your pizzas are being baked I'll say to bake the pizzas on a baking steel 3/8-inch thick or a stone at least 1/2-inch thick as hot as you can get your oven (allow at least 90-minutes for everything to come up to temperature before baking your first pizza).

Let us know if this mover your finished pizza characteristics closer to where you would like it to be.

[Re: Neapolitan Pizza - Puffy Airy Crust \(Canotto Style\)963](#)

When I was teaching in the AIB Baking Science and Technology class we used to make it when the students were in the large production shop, I don't think I have a copy of the formula anymore but if memory serves me correctly we used a spring wheat flour with 13.8 to 14.2% protein content, 1% oil, 6% compressed yeast, 1.75% salt, sugar 2%, vinegar (100-grain strength) 0.75%, water 72% (variable).

Mixing:

Use delayed salt addition mixing method.

Mix slightly past full development.

Targeted finished dough temperature is 63 to 65F (this is CRITICAL).

Fermentation time is 15 to 20-minutes.

Final Proof is hot and dry at 105F/50 to 55% R.H.

Bake at 400F

De-pan loaves for cooling immediately after baking.

Note:

We determined dough absorption experimentally by increasing it to the point where the proofed loaves would collapse during baking then back it down to a point where we no longer experienced collapse, with some lots of flour we were

able to use as much as 78% absorption.

The mixing time can be slightly reduced by withholding 10% absorption and mixing to full development, then adding the withheld water along with the salt and mixing it in during the last few minutes of mixing.

Handle the fully proofed dough GENTLY.

Hopefully I didn't forget too much!

[Re: English Muffin Bread.....?964](#)

Additionally, your IDY amount calculates out at 0.883% based on 453-grams of flour weight which is nearly 3 times the suggested amount of 0.3%. The IDY amount shown for the dough based on 1-Kg. of flour weight is correct at 0.3%. As Yael indicated the finished dough temperature is critical, especially when making dough in warmer climates, in your case you should be targeting a finished dough temperature of about 70F/21C, I would also recommend that you lightly oil each dough ball and place into individual plastic (bread type) bags, then twist the open end into a pony tail and tuck the pony tail under the dough ball as you place it into the fridge to cold ferment. I think this will work better for you than what you are presently doing. To use the bagged dough balls, remove from the fridge about 1-hour prior to use, roll the bag down around the dough ball and invert the dough ball over a floured surface allowing the dough ball to fall free from the bag onto the bench top, flour both sides of the dough and begin opening into a skin by your preferred method.

[Re: Help!!! Can't keep my dough balls as balls. 965](#)

I'd recommend starting with 250 to 275C for the deck temperature and use the same temperature on the top, then adjust the top temperature to give you the desired top pizza color characteristics once the bottom is baked, remember, not all cheese colors the same so your specific mozzarella cheese or cheese blend may color up entirely differently than that which someone else is using. The dough management as well as the dough formulation will also impact the way the crust bakes. The rule for baking pizzas is to get the bottom crust properly baked, then worry about the top of the pizza.

[Re: Correct Pizza Oven Temperature966](#)

Nope, it's not the radiant heat coming off of the aluminum wok, the oil will easily absorb that heat.

There is NOTHING that will give you a 72-hour shelf life on a yeast raised donut. If you want to have a 72-hour shelf life from a donut you have to make cake donuts, not yeast raised donuts.

[Re: Dunkin' Donuts Yeasted Donuts copycat967](#)

One thing I should point out is that what I fry donuts in is different from what you are frying them in, I'm talking about using a commercial donut fryer using a bit more than a cube of shortening (50#) so I have a huge amount of latent heat stored in all that hot oil while you are frying in what appears to be maybe just a couple pounds of oil so the temperature is not as consistent as mine is, with that said you may need to fry your donuts a little longer, you will sacrifice something in quality but that's the nature of the beast. The good news is that yeast raised donuts have a shelf life measured in hours so more than likely they'll all be gone in no time at all.
:chef:

[Re: Dunkin' Donuts Yeasted Donuts copycat968](#)

Hard fats like beaded mono-glycerides are not appropriate as they have a melting

point that is too high (typically around 136F) you need something with a melting point close to body temperature or it will impart a waxy mouthfeel to the finished product. Do you have a specific reason for wanting to use a more expensive spray dried product than just a blended plastic fat? The more processing steps that go into making a product the more expensive it usually becomes. The products you are looking at are typically used in specific applications like dry mixes.

[**Re: Adding high ratio of shortening/oil in pan pizza dough**](#)**969**

If you're going to use yeast your shelf life will need to be limited to not more than 15-days unless you use blast freezing. Without blast freezing, if you want/need more than 15-days shelf life you will need to use a par-baked crust to build your pizza on. As for the sauce, you will need to use as little water as possible while still being able to achieve spreading/application consistency. Some frozen pizza manufacturers will incorporate gums into the sauce (Ticaloid Lite from TIC Gums) to help control syneresis as the sauce melts during the early stages of baking, still it is a good idea to limit the amount of sauce used.

Regarding chemical leavening, a coated/encapsulated chemical leavening system such as Wrise is used only if you are making a bake to rise type of crust but since this type of crust also contains yeast you're back to blast freezing again.

So, what about the pizzerias that make a pizza, partially bake it, wrap it and sell it from a frozen case in their store? I think everyone will agree that they are not true restaurant/pizzeria quality pizzas but most will also agree that they are better than make delivered pizzas. This is OK at the store level where the food item is not exposed to the masses as it is at a supermarket, but once you take it to the supermarket you MUST ensure that the pizza is heated to an internal temperature of at least 160F and then get the product frozen as quickly as possible which may require that you have an effective HACCP (hazard analysis critical control point) plan in place that is being followed.

[**Re: Frozen dough recipes and stabilizers**](#)**970**

Before answering your question I would like to know what substrate the fat is sprayed on.

[**Re: Adding high ratio of shortening/oil in pan pizza dough**](#)**971**

Dustin;

Have you REALLY looked into this? I mean form a legal point of view?

Because your pizzas will be sold from a venue other than where they are made (pizzeria) you will have to have at minimum the following:

Ingredient declaration

Nutrition facts panel

Where the pizza is made (hard address)

Approved name (yes, there are laws regulating what you can call your pizza)

If there is any meat on the pizza it will need to be made in a USDA inspected facility.

You will most likely need to have special packaging (plain stretch wrap doesn't cut it).

The dough formula isn't anything special but you might want to consider moisture controlled vegetable toppings if you will not be blast freezing the pizzas. Blast Freezing= -30 to -45F, this can be done mechanically using an ammonia freezer or cryogenically using an industrial cryogen such as liquid carbon dioxide or liquid nitrogen.

Due to the UV light in the store you will need to have a full panel over the top of

the pizza or you will need to have a packaging film with a formulated UV barrier to prevent the toppings from fading in color which can happen quite rapidly.

[Re: Frozen dough recipes and stabilizers](#)**972**

Nothing special but just a good cheese flavor which I personally think is an improvement over just plain mozzarella is a blend consisting of 80% Grande WM mozzarella + 15% Parmesan and 5% Romano. After that, "the world is your oyster", begin experimenting with different cheeses to find what YOU like best for YOUR pizzas.

[Re: cheese blends](#)**973**

Can you break it down into smaller (5-pound) bags and store it in the freezer? If you can store it in the freezer for 6-weeks you can then transfer it to a container that can be tightly sealed and store it at room temperature for up to a year.

[Re: High-gluten flour in Nashville area](#)**974**

No, not unless your frying fat temperature is above 365F/185C, if you drop the fat temperature too far the donut will become dry or the inside will not be cooked properly. Optimum frying time for a yeast raised donut with a scaling weight of around 1.5-ounces will be about 1-minute and 45-seconds.

[Re: Dunkin' Donuts Yeasted Donuts copycat](#)**975**

All trumps is the "preferred" flour to use in New York as it gives the desired finished crust characteristics and the All Trumps flour used there also happens to be bleached and bromated. Does this mean that it HAS to be bleached and bromated? No, you can use just about any flour having 12 to 14.4% protein content to make a decent N.Y. style pizza. Stop worrying about the bromate, the residual "bromate" in the crust is measured in PPB (parts per billion). If you live in a metropolitan area you probably have more to fear from the air you're breathing. To answer your last question, little to none unless you are adamant about fermenting your dough for 5-days or more. Be sure to go back and read the discussion threads we just recently had on bromate in flour.

[Re: Bromated flour](#)**976**

Try keeping your hands wet during the rounding/balling process.

[Re: Thoughts on balling wet doughs](#)**977**

As a general rule, you only need to have a tightly balled dough if you are targeting much more than about 48-hours fermentation time in ball form. Rather than concentrating on balling tight or loose, it's better to concentrate on being consistent.

[Re: Shortest quality neapolitan dough](#)**978**

I agree, mix, (target finished dough temperature 75 to 80F), scale, ball, box and allow to ferment. The exact fermentation time as well as the yeast level will need to be adjusted to fit into your operating scheme in your mobile pizza operation.

[Re: Shortest quality neapolitan dough](#)**979**

Do NOT melt the shortening prior to addition to the dough.

[Re: Adding high ratio of shortening/oil in pan pizza dough](#)**980**

A lot of the answer to that question lies in what is being fried. Take donuts for example, new frying fat makes for crappy donuts so we ALWAYS seed the new

frying fat with a portion of the old fat. If you're frying things that put a lot of sugar, flour and seasonings into the fat you will need to filter the fast on a daily basis, but if you're frying things like French fries you can go several days between filtering the fat and because potatoes by themselves remove flavors from the fat you might be able to get away changing out the fat only once a week depending upon how much material you're putting through the fryer. In my opinion the worst thing to fry is tempura coated anything. Pieces of the coating are blown off in the fryer, and the coating is high in water content which can lead to hydrolytic rancidity, both of these combined means that you'll probably be cleaning out the fryer and filtering the fat daily while changing the fat on a much more regular basis than you would for any other product. It should go without saying that if you are frying fish and then want to fry donuts a change of the frying oil is in your near future.

As mentioned by others, oxidative rancidity is always an issue with frying fats, this is why commercial frying fats contain anti oxidants and anti foaming agents.

[Re: How many times do you reuse your frying oil?61](#)

Calzonemaker;

Different products exhibit differences in fermentation, when making pizzas there are a vast number of different flours of varying strength used to make the pizzas. If the pizza will be lightly loaded you can get away with a lot of over fermentation but if the pizza is to be loaded with a lot of toppings it may well collapse under the weight of those toppings if the dough is over fermented or fermented too much for the strength of the flour. Bread is all but intolerant of over fermentation because the dough is proofed to such a low density prior to baking and then it has to be handled when placing the bread into the oven, these conditions make the dough a prime candidate for collapse unless the flour is sufficiently strong or exhibits good tolerance to fermentation (a common characteristic of U.S. and Canadian wheats/flours but not always true for imported flours made from soft wheat varieties).

[Re: very sticky dough62](#)

beeuu;

The question that begs to be asked is how did you add the ADY and IDY. you told us how you added the CY but not the ADY and IDY.

[Re: yeast - fresh, IDY, ADY revisited63](#)

I'd go with upping the yeast a little to maybe 0.125%

[Re: Need help proofing my Sicilians 64](#)

I use left over turkey all the time, even tried it a time or two with stuffing. Use both just like any other added topping ingredient. For a cheese topping I am partial to using a blend of mozzarella and ricotta applied in dollops. I've even added the mashed potatoes too, just place them on the pizza in dollops like the ricotta. For this type of pizza my preference leans towards using a white sauce rather than a red sauce since it ties the pizza together better than a red sauce which just seems out of place.

[Re: turkey pizza with leftovers?65](#)

Your starter might be too strong or your flour might not be strong enough to handle the starter strength under those conditions.

Hard to tell with limited data.

[Re: Dough is ripping while stretching, help!66](#)

Flour: 100%
Salt: 2.5%
IDY: 0.375% (variable depending upon dough management procedure)
Water: 60%
Add water to mixing bowl, then add the salt, flour and IDY.
Mix at low speed for 2-minutes, then mix at medium speed just to form a smooth dough.
Target finished dough temperature 75 to 80F.
Immediately scale and ball.
Lightly oil dough balls and place into individual fermentation containers.
Place in fridge UNCOVERED until INTERNAL dough ball temperature reaches 50F, then loosely cover/lid the containers.
NOTE: THIS PART MAY CHANGE DEPENDING UPON WHICH "00" FLOUR YOU HAVE.
Allow dough balls to CF for 24 to 48-hours.
Remove from cooler and allow dough balls to warm to 50 to 60F INTERNAL dough ball temperature.
Open into skins for immediate use.
Note: There are MANY different ways to work with "00" flours, this is just one of them.

[Re: Caputo 00 thin crust dough recipe](#)**67**

Use a stem aka dial type thermometer to measure the INTERNAL dough ball temperature after the CF period. When the internal dough ball temperature is in the 50 to 60F/10 to 15.5C range it is ready to open into a skin for immediate use. From what you have said I'm guessing that you are allowing the dough to get too warm before opening it into a skin.

[Re: Too stretchy dough](#)**68**

Peter is absolutely correct. Learn the basic and easy to make pizzas first using common, off the shelf ingredients. You will be able to hone your pizza making skills while building your confidence, then, using your new gained skills you will be able to venture out into other types of pizzas or upping the game by experimenting with different ingredients above all else, remember to change only one thing at a time when it's time to begin experimenting, go slow and easy and smell the pizzas along the way, the rewards are delicious! :drool:

[Re: Most Important Things for Beginner's to Focus On](#)**69**

Walter;
What would we ever do without duct tape? :-D :-D
[Re: Rounder and divders](#)**70**

I think I found our why your pizza slice was wet and soggy!!! :-D :-D :-D :-D
[Re: How does dough ball size affect kneading?](#)**71**

With American style pizzas using approximately 0.375% IDY (instant dry yeast), with effective dough management and a room temperature in the 70 to 75F range we will typically allow the dough balls to set AT room temperature until they reach 50F/10C before we begin opening them into skins, once we begin opening the dough balls into skins they will be good for the next 2.5 to 3-hours. Any unused dough balls are not put back into the fridge as this creates an inconsistency for those dough balls on the following day (consistency is the name of the game), instead, we convert those dough balls into things like bread sticks and garlic knots

which can be par-baked and used on the following day without any issues. Additionally, you can also use left over dough balls in your new dough but the amount that you add should not exceed 15% of the new dough weight.

[Re: Pizza Dough Storage & Handling Questions](#) 72

In the Philadelphia area there was a pizzeria where the owner mixed all of his dough by hand. His doughs were based on a 50# bag of flour, however he did not knead the dough in the truest sense of the word, instead he just combined the ingredients by hand and let biochemical gluten development do all the work for him. If when you say "knead" you mean it in the literal sense a dough sized on 20-pounds of flour weight will probably all you will want to wrestle with and even then you will be on the fast track to achieving your secondary goal of developing arms like the village blacksmith. Anything smaller just gets easier.

[Re: How does dough ball size affect kneading?](#) 73

Yael;

I used to say that knowledge is like a fine wine, if it's not shared it's just wasted.

[Re: longer RT sourdough fermentation](#) 74

We really need to know more about your dough formula and how you're managing the dough.

[Re: Neapolitan crust isn't puffing up](#) 75

Before we go off on a tangent, you're talking about total dough size/weight....right?

[Re: How does dough ball size affect kneading?](#) 76

Without knowing the strength of your sourdough starter it's impossible to answer your question. The best advice I can offer you is to make three doughs at 4%, 8% and 12% starter and see which one performs the best for you under YOUR specific conditions.

[Re: longer RT sourdough fermentation](#) 77

Yael;

I've never been so fussy that I didn't sneak a piece of the overturned pizza after evaluating it, like we used to say in the lab, it's all in the name of research! :-D :-D

[Re: Question about cutting the pizza](#) 78

Par-baked crusts are always going to give you a finished pizza with a lower moisture content in the crust. If you want to avoid that you will need to par-bake the crusts with some steam in the oven or add a gum to help retain moisture in the baked crust. We recently had some discussion on this very topic which you might want to check out.

[Re: dried out crust after parbaking](#) 79

Par-baked crust, or anything else for that matter, is actually fully baked, it has to be in order to avoid collapse during cooling. If you are getting too much color during the par-baking phase you will need to REDUCE the baking temperature and possibly extend the baking time. The idea in par-baking is to achieve an internal dough temperature of 190F. Once you reach that IT the dough is fully baked and should have minimal crust color development.

[Re: dried out crust after parbaking](#) 80

With pan style pizzas using shortening is preferred over oil, the best way to add it is to have it at a temperature between 70 and 80F and just add it right on top of the flour when you begin the dough mixing process. If the amount of shortening is 10% or more it is advisable to withhold the shortening until after the dough has come together in the mixing bowl, then add the shortening and mix just enough to thoroughly incorporate it.

[**Re: Adding high ratio of shortening/oil in pan pizza dough981**](#)

Dough enhancer is a very broad term, I guess we might call anything added to the dough that enhances it in some way a "dough enhancer" these might include:

dead yeast (glutathione): Dough Relaxer

diastatic or non-diastatic malt: Crust color/flavor/food for the yeast

vital wheat gluten: Strength

calcium sulfate: Reduces stickiness

from a commercial stand point enzymatic oxidizers are also used: Strength

some might even include ascorbic acid: Strength

vinegar might be referred to as a dough enhancer too: Accelerates fermentation

It all depends upon that you want the dough enhancer to do, then you select the best product for that function.

[**Re: Dogh Enhancer982**](#)

The traditional way of making bagels is to mix, form, cold proof on bagel boards overnight, pull from the cooler and allow to rest at room temperature for 20 to 30-minutes, transfer to the boiling kettle and stir, until the bagels all float, then transfer to a rinse station where the bagels are flushed with cold water and immediately topped if desired and placed onto wet baking boards (redwood) and baked for a couple of minutes until a firm skin is formed on the bagel, they are then turned off of the boards (inverted) onto the oven deck to continue baking.

[**Re: Baking soda and Pretzel983**](#)

Bagels are either steamed or kettled (boiled) but not actually boiled as the water temperature is only 200F, and just plain water is used. After kettling they are allowed to dry for a minute or so and then baked with a turn about mid way through the baking process, pretzels are just run through the alkali solution (2% lye) and then salted and baked. For the crispy pretzels they then go through a kiln drying process which is a pass under the oven to allow for a more controlled drying process (about 20-minutes), they are then taken directly to packaging.

Steamed bagels are made using a rotating rack oven, steam is introduced into the oven for the first 15 to 20-seconds, the door is then opened to evacuate the steam and the bagels are baked for about 18 to 20-minutes at 450F. The difference is that kettled or traditional bagels as they are known are tough and chewy while steamed bagels are much more tender eating, for this reason the steamed bagels are much more popular for use when making bagel sandwiches.

[**Re: Baking soda and Pretzel984**](#)

Travis;

Just something to watch for. Pineapples contain a very powerful reducing enzyme (Bromelain) which is very similar to papain. These enzymes are effective at hydrolyzing protein and very low levels. I don't know if the pH of the starter will inactivate the bromelain or not but it is something to be aware of. If you use the starter and find that the dough becomes unusually soft and extensible this might be the cause. let us know how it works for you.

[Re: Hidden dangers of old starters?985](#)

Tim;

I wrote about this in one of my articles some time ago. Here are the things to do to improve the quality of a DELCO pizza;

- 1) Lightly oil the skin prior to application of the sauce.
- 2) Use sauce sparingly.
- 3) Use vegetable toppings sparingly.
- 4) Bake pizzas as LONG as possible to both dry out the pizza and develop the thickest crust as possible.
- 5) Immediately after baking place on rack to steam-off for a minute before boxing.
- 6) Use some type of sheet in the box to hold pizza off of the bottom of the box.
- 7) Make sure box has steam vents and that the vents are opened.
- 8) Encourage customers to reheat/re-crisp the pizza when they get it home.
- 9) When it comes to oven selection, air impingement ovens are by far the best choice if DELCO pizzas are in your future. The focused airflow of these ovens is a decided benefit to achieving the best bake and driest pizza possible for this application.

[Re: My pizza gets soggy not crunchy after cools down986](#)

Also check out any scrap yard that take metal in your area, we have one near us and I've found some great buys there. For a few extra bucks they'll even cut it.

[Re: If I wanted to just buy a 1/2" pizza steel, where would I do that for the least 987](#)

Five to eight percent shortening will be about the limit. As for why the dough appears to ferment faster with fat the answer is, it doesn't but the fat both lubricates the dough for easier expansion and it also coats the cell wall for improved gas retention so the dough retains more gas, making it appear larger.

[Re: Chicago tavern style needs improvement988](#)

What you have described is pretty common for delivery/take away pizza. Delivery pizzas are best baked as long as possible and with a ripple sheet or Pizza Savor mat in the box to hold the pizza up off of the bottom of the box, we've discussed this here a number of time in the past if you care to search the archives. Your best bet might be to educate your customers to reheat the pizza once they get it home, this will refreshen as well as re-crisp the pizza for maximum enjoyment.

[Re: My pizza gets soggy not crunchy after cools down989](#)

Do you mean autolyse and hydration? Hydrolysis is a totally different thing not related to pizza making.

If so, you can mix water and flour together to allow the flour to better or more fully hydrate prior to the actual dough mixing process. This is beneficial when making dough with whole-wheat flour or making a multi-grain dough. In this case the flour and water are typically allowed to set for about an hour. An autolyse, on the other hand, is similar but it is allowed to set for anything from one to several hours (more typically several hours) which allows the flour to fully hydrate and it also allows for enzymes in the flour and yeast to begin working making for an easier to handle dough and some will say a better flavored finished product. The autolyse method is especially beneficial when making dough with a high (70%+) absorption.

[Re: What is the differense between Autolysis and hydrolysis?990](#)

Your ADY is a bit on the high side for what you are wanting to do, I'd suggest

dropping it back to 0.3%. Additionally, you don't say what the finished dough temperature is but from what you are describing it sounds like it is possibly too high (hot), try adjusting the water temperature to give you a finished dough temperature of 70F/21.1C.

[Re: Blistering when balling](#)991

Pictures? It sounds like the dough might have quite a bit of fermentation on it at the time of scaling and balling, a picture would help.

[Re: Blistering when balling](#)992

One more thing, the strength of your flour will also play an important part in determining if YOUR dough will still be good several days down the road.

[Re: Storing dough in fridge.. How long?](#)993

A lot of the answer to your question pivots around the finished dough temperature, the amount of yeast used in the dough formula, and overall how well the dough is being managed. Every dough is different in this respect, the best advice I can give you is to save one or two of your dough balls for testing with a few more days of CF time. That's the only way you will know for sure.

[Re: Storing dough in fridge.. How long?](#)994

The next time you make them open them up a bit more to get a better shape, then try dipping the tops in sesame seeds right after the caustic solution, makes for a great flavor!

[Re: Baking soda and Pretzel](#)995

We typically use 10-ounces of dough to make a 12-inch N.Y. style pizza, this calculates to a dough loading of 2.4778-grams per square inch. A 20-inch pizza has 314-square inches so $314 \times 2.4778 = 778$ -grams. So based on this a good dough weight for your 20-inch N.Y. style pizza would be 778-grams.

[Re: 20" \(50cm Pies\) im up to 24oz \(700g\) dough balls to get up to size](#)996

Vacuum sealing it the key to getting long term storage from an opened package of IDY. New packages are either gas flushed or vacuum sealed.

[Re: Yeast storage and longevity](#)997

Norma;

I've heard of it but never used it.

[Re: Baking soda and Pretzel](#)998

Let me see, August 11, 2018 to August 11, 2019 = 1-year and August 11, 2019 to August 11, 2020 = 2-years, yep, just as I guessed, it's still good. Your observation is correct in that as the IDY ages it loses its potency and you need to continue adding more and more of it. From a commercial application point of view this is totally unacceptable but for home use it isn't necessarily a game changer. Once you open the package all bets are off the table when it comes to shelf life as there are just sooooo many contingencies that might impact the shelf life.

When I was running the bake lab at AIB we made it a habit to NEVER hold an opened package of IDY for more than 5-days, the reason for this is because we saw a difference in performance already at the 7-day mark. I believe most manufacturers will suggest holding an opened package no more than 14-days, but this again is for commercial application, not for home application. There are huge differences in performance expectations between experimental/research,

commercial and home applications.

[Re: Yeast storage and longevity](#)**999**

A number of years ago one of the major pretzel manufacturers got the lye solution too concentrated which resulted in residual lye on the surface of the pretzels and caused a recall of the product as consumers were complaining of a burning sensation on their lips after eating the pretzels. Every once in a while you will experience this same burning sensation when eating perfectly "normal" pretzels, this is due to the water in the lye solution evaporating to cause a slightly too concentrated solution having the same results but to a much lesser degree. The most concentrated lye solution purchased by bakeries is 20%, in the dry form it is much too dangerous due to its propensity to dust into the air while being transferred/scaled.

[Re: Baking soda and Pretzel](#)**1000**

It only takes 0.25% of a 20L malt powder to replicate the level of malting flour receives at the flour mill, anything over that will be converting a significant amount of starch to maltose sugar which is why you found it necessary to use less malt powder than sugar, the downside to it thought is the inherent stickiness of the dough due to the formation of excess maltose.

[Re: Diastatic malt vs sugar](#)**1001**

Please define "higher absorption" in bakers percent.

[Re: Chicago tavern style needs improvement](#)**1002**

Brent;

That's exactly the same as for honey. ^^^

[Re: Diastatic malt vs sugar](#)**1003**

The manufacturers used to have a 2-year shelf-life on it at 70F storage temperature but a number of years ago they rolled it back to 1-year, I think the reason being that it was too difficult for merchants and users to keep track of the age over such a long storage period. Unopened, you should be good for 2-years at 70F.

[Re: Yeast storage and longevity](#)**1004**

We have addressed this question before, when storing either ADY or IDY in the refrigerator or in the freezer it is HIGHLY recommended that the yeast be removed from the fridge or freezer and allowed to come to room temperature BEFORE opening the container. Moisture will lead to early loss of the yeast so opening the container ONLY after it has reached room temperature will reduce the condensation issue thus reducing the moisture accumulation on the yeast and result in better long term storage of the yeast. By the way, it is NOT recommended to remove the yeast from the original packaging if using only a portion of the yeast, instead, fold the packaging down tightly to the yeast, secure with tape or rubber band and refrigerate or freeze. Air will also cause the yeast to deteriorate and this eliminates much of the air in the package.

[Re: Yeast storage and longevity](#)**1005**

Rather than using "melted" butter, just use "softened" butter, putting melted butter in the fridge is counter productive. As for achieving the targeted finished dough temperature just use colder water, some use water that has been stored in the fridge overnight while others find that they need to use a little crushed ice in the

water too. I don't know how else to explain the appearance of the dough when it has been properly mixed except to say that it is just mixed until the dough has a smooth appearance which is a very good visual indicator that the dough has been sufficiently mixed when you are going to use 18 to 24-hours of cold fermentation. It is impossible for me to speculate what speed to mix the dough at using your specific mixer except to say that you should use the highest speed possible without fear of over working your mixer.

[Re: Cinnamon rolls](#) **1006**

Try using shortening rather than oil but be aware that the dough will still cling to the shortening, most pizzerias use the plastic dough boxes which don't pose this problem.

[Re: Dough sticking to dough pans](#) **1007**

I'm assuming your malt powder was non-diastatic?

When using honey remember that the darker the color the more robust the flavor will be. In the baking industry we use honey that is as dark as black coffee.

[Re: Diastatic malt vs sugar](#) **1008**

Yael;

When making pretzels you don't need to use an egg wash for color. The alkaline wash will give you both color and shine, the stronger the alkaline wash the greater the color. We typically used a 2% sodium hydroxide solution (which is what is used commercially). One might say that the only real difference between a bagel and a pretzel is alkalinity of the water in which the bagel is "kettled" in. When pretzel crusts were all the rage we made them by brushing the edge of the skin with the 2% sodium hydroxide solution and then applying a light application of coarse pretzel salt just prior to baking. We made the pretzel buns by the exact same manner.

[Re: Baking soda and Pretzel](#) **1009**

Gotta admit, that's a good lookin' pizza! :drool: :drool: :drool:

[Re: Serving up pan pizza - soggy crust woes.](#) **1010**

Even with an electric oven it is highly recommended that you have some kind of ventilation in your garage or eventually you're going to find everything covered with a sticky layer of goo. You might be surprised to find out what goes up the stack in an electric oven.

[Re: Commercial oven for garage, gas vs electric?](#) **1011**

Yep, it's the "nature of the beast" to get soft VERY soon after exiting the oven. If you are baking the pizzas at home and also happen to be the Chief Cook, Bottle Washer, CEO, CFO, and President of pizza making endeavors you can do whatever you want and deviate from the classical Neo type pizza to something that better fits YOUR likes (that's actually the best part of making pizzas at home), so by simply reducing the oven temperature and baking longer you can introduce a more crispy nature to the finished crust and the crust will retain the crisp for a longer period of time, this is the experimentation that we all find so interesting. The more you experiment the more you understand about pizza and the more experimenting you will want to do (it's an endless cycle) but you will find few here who are complaining about it.

[Re: Neapolitan pizza goes Tough and rubbery after 15 minutes?](#) **1012**

Saying that you use Caputo "00" flour really doesn't help very much as there are different types of Caputo "00" flour, perhaps you are using one which isn't designed to tolerate more than 12-hours of fermentation? It would be good to know the actual finished (mixed) dough temperature as well as exact ingredient weights or amounts in bakers percent. What kind of mixer are you using? When you bulk ferment, what kind of dough weight are we talking about?

[**Re: Flat Pizza balls**](#)**1013**

It's my experience that this is a pretty common issue with aluminum fermentation pans. I used them when I was at AIB and we always had to scrape the dough off of the pan. Plastic, in my opinion, is a much better alternative.

[**Re: Dough sticking to dough pans**](#)**1014**

How about the time I set a series of experimental doughs and then went to lunch with aspirations of conducting the baking experiments that afternoon after lunch, upon my return I got everything ready and pulled the first dough only to find it looking much like it did in the morning, OMG! Are they all like this? Yep, everyone. Forgot to add the yeast.

Almost as bad as the time when I set sponges in the morning and went over to the lake (Michigan) as AIB was located only 200-yards from Ohio Street Beach, I was watching the kids playing on the shore and my eyes got heavy, very heavy, when I woke up it was quiet, the kids were gone and it was almost 4:00 p.m. Oops! Those sponges, well lets just say that they were very well fermented and yes, there was a mess to be cleaned up as they all over flowed their containers.

[**Re: Diastatic malt vs sugar**](#)**1015**

If the donuts were wet coming out of the proofer the relative humidity was too high in the proofer, remember that you only want a R.H. in the 75 to 80% range (favoring 75%) at this humidity the proofed donuts will have a dry but soft outer skin on them.

[**Re: Dunkin' Donuts Yeasted Donuts copycat**](#)**1016**

Traditionally, All Trumps flour is used but the truth is that just about any good bread type flour will work well. Here is a good starting dough formula:

Flour: 100%

Salt: 1.75%

Olive oil: 2%

IDY: 0.375%

Water: 63% (70F)

My Dough Management Procedure is presently posted here in an active thread, I suggest using the plastic bag procedure with a cold fermentation period of 48-hours.

[**Re: pizza dough for ny style piza**](#)**1017**

QJ;

Sometimes it's also the BTU of the burner or the way the flame is adjusted that can result in this issue.

[**Re: Chicago tavern style needs improvement**](#)**1018**

djenks;

I'm not sure I fully understand your question, but I do suggest increasing the salt and shoot for the targeted finished dough temperature. Then go straight from the

mixer to the bench for scaling and balling, then bag and into the cooler.

Here is another option for a truly outstanding Chicago style crust.

Put water in mixing bowl (70F).

Suspend the IDY in a small amount of 95F water then add to the water in the bowl, no need to activate, just hydrate.

Add salt and sugar IMMEDIATELY followed by the flour.

Mix at low speed for approximately 1.5-minutes (yes, you read that right). The "dough will look very shaggy" with lots of dry flour present.

The dough is properly mixed when you can grab a hand full and press it together to form a crumbly ball (it will NOT be cohesive).

Scale to desired weight, form into "puck" shape as you would if making a pie crust.

Place into individual plastic bags as you presently do.

Cold ferment for 24 to 48-hours.

Remove from cooler, allow to warm to 50F (internal ball/puck temperature).

Turn out of the bag (the dough will be much more cohesive now). Do not re-ball, just flatten and begin forming.

Form into a skin using a dough sheeter or rolling/pastry pin.

Dress to the order and bake.

NOTE: This dough has no added oil.

I discussed this procedure quite some time ago here if you want to research it.

[Re: Chicago tavern style needs improvement](#) **1019**

If you are looking for more of a "corn" flavor in the finished crust try replacing 50 to 100% of the corn meal with Masa Flour/Maseca.

[Re: "San Francisco" style cornmeal attempt](#) **1020**

One of the very first things I'd do to address the flavor issue is to increase the salt level to 2%, then at the same time change the dough mixing procedure by putting the water in the mixing bowl first, then the salt and sugar (no need to stir) followed by the flour and IDY. Mix at low speed just until you don't see any dry flour in the bottom of the bowl, then add the oil gradually, mix 1 additional minute after all of the oil has been added, then go to the next highest speed and mix for 8 to 10-minutes. You don't say anything about the finished dough temperature, this is a critical aspect of effective dough management. I'd suggest targeting 75 to 80F for 48-hours CF.

[Re: Chicago tavern style needs improvement](#) **1021**

If you didn't put any yeast in the dough you might be disappointed. :-D

[Re: Diastatic malt vs sugar](#) **1022**

The key here is to make sure it gets reheated to a temperature above 160F which isn't always the case on the top of the slice. This can be a pretty good case for a small air impingement or IR oven for reheating those slices especially if you are having a hard time dealing with a FSI.

[Re: Best Practices for Pizza by the Slice: Food Safety & Taste](#) **1023**

We did all of our research on a stone deck in a combination wood and gas fired commercial pizza oven that was a full 6-inches thick. I can see where different deck materials as well as different deck thickness would affect this. Good point.

[Re: Diastatic malt vs sugar](#) **1024**

Non diastatic malt is nothing more than "malt sugar" while diastatic malt is enzyme active alpha amylase primarily but other enzymes are also present which hydrolyze

wheat starch into maltose which is then further hydrolyzed into glucose by the enzyme (maltase) in the yeast which is then metabolized by the yeast as a nutrient to support fermentation/yeast activity. Too much malt and a wood fired oven baking at very high temperatures is generally not considered a match made in heaven as the crusts have more than a slight tendency to burn. If baking at less than 650 to 700F this may not be as much of a problem.

A typical use level for 20L dry malt powder is 0.25% in an un-malted flour.

[Re: New member and malt powder question 1025](#)

I also like to do it out of the bowl using a scraper in one hand to help lift the dough and stretch it for folding.

[Re: On stretching and folding wetter doughs 1026](#)

If baking on the deck, about 650F, even at that the crust might develop color too quickly for some pizzas.

[Re: Diastatic malt vs sugar 1027](#)

Thickness Factor/Dough Loading = dough weight divided by pan surface area in square inches.

$15.5 \times 12 = 186$

22-ounces divided by 186 = 0.1182795

Dough Loading Factor: 0.1182795 or to put it another way, you have 0.1182795-ounces of dough per square inch of pan surface area.

[Re: Serving up pan pizza - soggy crust woes. 1028](#)

And don't forget to put a wet towel in the oven too, otherwise just heating the air will drive the R.H. down allowing a crust to form on the dough (something you don't want).

It is very easy to make your own donut proofer too, all you need is a box, a light bulb and a wet towel, use a pair of stem type thermometers for measuring R.H. with a couple of ventilation holes cut into the box to control temperature and humidity you're good to go.

[Re: Dunkin' Donuts Yeasted Donuts copycat 1029](#)

Sure, here's how it's done.

A good dough weight for a 12-inch pizza is 10-ounces. The surface area of a 12-inch circle is $\pi \times R^2$ (you might remember that from high school math), so $3.14 \times 36 = 113.04$ -square inches. By dividing dough ball weight by surface area we get the dough loading per square inch (10-ounces divided by 113.04 = 0.08846-ounces per square inch).

A 6-inch pizza has ($3.14 \times 9 = 28.26$ -square inches) Now all we need to do is to multiply the surface area of the 6-inch pizza by the dough loading (0.08846) to find the weight of the dough ball needed to make our 6-inch pizza ($28.26 \times 0.08846 = 2.4998$ -ounces) We can round that off to 2.5-ounces.

Each dough ball should weigh 2.5-ounces to make a typical 6-inch thin crust pizza skin.

Can the dough ball have a different weight? Sure it can, it's YOUR pizza so you can make it whatever you want but I think 2.5-ounces is a reasonable starting point that will make a finished crust about the thickness of a Domino's thin crust.

[Re: Six Inch Individual Pizzas 1030](#)

That would be my recommendation. Yeast raised donuts are final proofed at 85 (29.4C) to not more than 90F (32.2C) at between 70 and 75% relative humidity for

40 to 60-minutes. Total frying time will be just under 2-minutes total for both sides.

[Re: Dunkin' Donuts Yeasted Donuts copycat](#)**1031**

Most will fully bake the pizzas, hold in a temperature/humidity controlled cabinet and reheat for the customer. I like to add a little additional cheese for flavor and appearance, but that's just me. In the end you will want to develop a plan and then pass it by your food safety inspector the his/her blessings, after all, in the end they will have the final say in the matter.

[Re: Best Practices for Pizza by the Slice: Food Safety & Taste](#)**1032**

When dealing with un-malted flours you will typically see a slightly greater tendency towards developing more crust color with a higher protein flour than a lower protein flour due to the fact that protein participates in the browning reaction.

[Re: Diastatic malt vs sugar](#)**1033**

That is a VERY LOW temperature (130C/266F) for frying donuts at. The lowest I've ever seen used was 340F/171C.

[Re: Dunkin' Donuts Yeasted Donuts copycat](#)**1034**

In a scenario like that the dough will continue to ferment but because it's warmer and continuing warm (due to heat of metabolism) the fermentation rate will also continue to increase. The result will soon be a dough that is difficult to shape as it becomes overly extensible and in a severe case it will become very weak making opening it into a skin without having it tear or develop holes all but impossible. In most cases dough balls that have been allowed to ferment too long can be salvaged by re-ballng them BUT remember that it may take several hours for the dough to relax sufficient for it to be opened again. A much better option (one that is commercially practiced) is to go ahead and open the dough balls into skins before they reach this point, place the opened skins onto pizza screens and store in the cooler/fridge (covered to prevent drying) until 20 to 30-minutes prior to time of use. To use, remove from the cooler (keeping covered) and allow to warm AT room temperature for 20 to 30-minutes, remove from the screen and touch-up the dough skin, then dress and bake to the order. A lot of pizzerias do this to enable them to keep up with the rush periods when they tend to fall behind on opening skins.

[Re: How long can proofed dough sit at room temperature.](#)**1035**

Using flour with too low of a protein content can result in an overly tender finished donut, deleting the whole egg will reduce the richness of the finished donut. 0.8% IDY should work OK.

Remember that powdered sugar is made from dextrose, not sucrose which is why powdered sugar exhibits a cooling effect in the mouth and the flavor isn't overly sweet.

[Re: Dunkin' Donuts Yeasted Donuts copycat](#)**1036**

You might try this for your mixing procedure, put water in mixing bowl first (65F), then add the flour and all of the dry ingredients and mix at low speed just until you don't see any dry flour in the bowl, add the oil and mix at low speed for 1-minute, change to the highest speed your mixer will handle the dough at and mix 8 to 10-minutes, or until the dough just begins to look smooth. then scale/ball and cold ferment for 24 to 48-hours, after CF allow the dough to warm to 55F at room temperature (this is the INTERNAL dough ball temperature), it will take about 90 to 120-minutes. Then proceed with your usual process. Keep us posted.

[Re: Serving up pan pizza - soggy crust woes.](#) **1037**

Be sure to remove the pizza from the pan IMMEDIATELY after you remove the pizza from the oven and place it onto a wire cooling rack for a minute or so to allow the toppings to set-up, then transfer to a cutting surface and cut into desired slices, serve immediately.

Additionally, can you share your dough formula as well as the dough management procedure and baking procedure with us? Perhaps there is something there that we can help you with to achieve a crispier crust.

[Re: Serving up pan pizza - soggy crust woes.](#) **1038**

The Thunderbolt was a "plain Jane" Ford Fairlane with a 4-speed and just a single bucket seat, no passenger seat or back seat, battery was located in trunk over right rear wheel (Ford still didn't have a decent locking rear end). I took off all of the 427 badges and replaced them with 289 badges. I ended up putting in a second bucket seat and replaced the driver's harness with a lap belt and then add a rear seat.

Spent a lot of time under the hood adjusting valve lash. Spark plugs were a bear to replace so I added a Delta Electronics C.D. ignition system, aside from that it was "stock". Can't tell you how many 289 Mustangs and 289 H.P. Fairlanes got "dusted" by it, even did the number on some "goats" (Pontiac 389 GTO's), even did in a 396 Nova SS and my buddy's 383 Plymouth. The most expensive part of that car was the cost of tires! Ran Blue Streaks on the rear for traction in the summer and usually went through at least two sets every summer. Tire rotation on the rear was done every two weeks.

The beast made the Shelby Cobra look very refined!

[Re: My First Car was](#) **1039**

Paulrevere73;

Here in Kansas we call that camouflage. :-D

[Re: My First Car was](#) **1040**

You're not going from 500 - 550F to room temperature, you are only going from the suggested platen and head temperatures of around 250 to 300F and pressing for +/- 5-seconds.

RS-190 aka dead yeast is available from Red Star Yeast/Lesaffre. Contact Sandi Cazalet at <s.cazalet@lesaffre.com> / <www.lesaffreyeast.com>.

[Re: Mimicing whole-sale cracker thin-crust dough](#) **1041**

A 1954 flathead V-8, then a 1956 Ford Crown Victoria V-8, then a 1960 Ford Thunderbird, Then a 1964 Ford Sprint with the 289 V-8 crate engine option, after that it was a 1966 Ford Thunderbolt 427, then a 1969 Shelby Cobra, after that I grew in a different direction and it was a 1972 International Scout II, then a 1979 Jeep Renegade, then a 2001 Dodge 2500 Pickup (which I still have) and presently also have a 2014 Jeep Patriot. In addition, in 2005 I bought a Dodge Dakota as my daily driver (a real piece of CrXX) plagued by engine, electrical, body rust and mechanical issues its entire life, three years ago it gave up its life to save mine when I hit a patch of unseen black ice on the Interstate, it was replaced by the Patriot which has served me VERY WELL. I can also tell you about all of the cars my wife has had too including the 1967 VW Beetle that I retrofitted with a 20-gallon gas tank up front (it got an honest 40 m.p.g.) giving it tremendous range during the gasoline shortage years.

Cars are just one of those things us guys don't ever forget.

[Re: My First Car was](#) **1042**

That's the key here, whatever is used to press form the skins needs to be able to maintain that temperature for the duration of the dwell time.

It might be as easy as two thick steel plates placed into the oven to pre-heat and then placing the partially opened skin onto one of the plats (don't forget to oil it first) and immediately placing the second (oiled) plate on the skin and pressing down on it for a count of 5 or more seconds, then removing the plate and peeling the formed skin off of the bottom plate. I've personally never ventured into this territory as I've always had access to a multitude of different hot and cold presses to work with. The first thing to do is to study the different hot presses available (AM-Manufacturing) and I think Dough-Pro also has one with both a heated head and platten, though I may be wrong?

In my mind this is what I see, two steel plates of desired diameter, bottom plate is 1/2-inch thick and top plate is 3/8-inch thick. Top plate has two sturdy handles welded onto it to allow it to be evenly pressed with full upper body weight down onto the bottom plate (with the dough trapped between them), after the dwell time the top plate is lifted off of the dough and the skin is manually lifted from the bottom plate. Will it work? Only one way to find out.

[Re: Mimicing whole-sale cracker thin-crust dough 1043](#)

When the crusts are commercially made on a wholesale basis the entire skin is subjected to the heat of the hot press (about 300F bottom and 250F top). The dough will need to be very soft and extensible, remember that it has to go from a ball to a fully formed skin in something between 1 and 2-seconds. Better than your cast iron pan approach might be to try a couple of Pyrex pie plates, using a rolling pin, open the dough ball to about the diameter of the bottom of the pie plate, then place the top plate on the dough and carefully press the dough between the two pie plates, leave it set for a minute or so (commercially the dwell time is only about 5-seconds) but you're not holding it under 800 p.s.i. pressure under heat so you need to work outside of the box, when the dough has been pressed between the two plates (dwell time) long enough it will release from the plates without too much difficulty and have a slightly glossy appearance, then it goes directly to the oven for par-baking.

I think you might be plowing a virgin field so please keep us posted on your progress.

[Re: Mimicing whole-sale cracker thin-crust dough 1044](#)

TNT Crusts makes their own hot presses but they are copied after the AM Manufacturing commercial hot presses, if you want to see how the crusts are formed just Google (Am Manufacturing dough presses), there are a number of links to look at but one has a video that you might be interested in seeing. I won't go into much detail but these dough receive almost no fermentation and they do use a reducing agent (RS-190) aka dead yeast to facilitate pressing, after pressing the shins are par-baked to set the structure, it is then important to allow the crusts to age for at least 24-hours before using.

The chemical leavening (SALP and SODA) are in the form of a fat encapsulated chemical leavening system which we have previously discussed here and I've written an article or two on it also. The commercial name for this product is "Wrise", manufactured by Wright Enrichment Company.

[Re: Mimicing whole-sale cracker thin-crust dough 1045](#)

You want the frying fat at 365F and the donuts will look better after the frying fat has some age on it. New/fresh frying fat doesn't do much for the appearance of the

donuts. This is why those in the business of making donuts always seed their new frying fat with 15% of the old fat.

[Re: Problem of yeast donut - many bubbles](#) **1046**

There are some good charts here that will allow you to predict the amount of yeast needed for specific room temperature fermentation, if you cannot control the room temperature your only other option, in this case, is to adjust the yeast level based on the room temperature. But be aware that there are short comings to this too in that a reduced yeast level can affect the oven spring, especially if your pizzas tend to be heavily loaded.

[Re: Complications with dough management](#) **1047**

Try par-baking with 1/2 of the sauce, then remove from oven and place on screens in a wire tree rack to cool. Does not need refrigeration. At the event all you need to do is to apply the remainder of the sauce and dress to the order, you can do that faster then the pizzas will bake and you will get the freshest pizza. Reheating a par-baked pizza is OK at best.

[Re: Large Pizza Party - prebaking pies?](#) **1048**

Your salt level is low too at just 1.368%. A better salt level would be something in the 2 to 2.5% range. Since salt helps to control the fermentation rate as well as strengthen the dough this would be a step in the right direction too.

[Re: Starter with ADY trouble](#) **1049**

In loaf bread bleached flour produces a brighter, whiter crumb color, but in pizza the crumb structure doesn't lend itself to seeing this since it is so thin and more open/porous as well as most of the time being smeared with sauce and/or toppings due to cutting. So for all practical purposes it can be said that bleaching has no impact on pizza dough or the finished crust.

[Re: Diastatic malt vs sugar](#) **1050**

That's the best part of making your own pizzas at home, you can make them the way YOU like them, and remember, if YOU don't like it you know who to blame. :-D

[Re: Opinions regarding cornicione of the pizza](#) **1051**

Here is a working example:

Flour weight: 800-grams

Ingredient percent: 0.375%

The math using your calculator: 800×0.375 (press the "%" key and read the ingredient weight in the display (3-grams) NOTE: Ingredient weight will ALWAYS be in the same weight units (pounds, grams, kilograms, etc.) that the flour is shown in.

To find the total dough weight:

Find the sum of all of the ingredient percentages, then divide by 100. Multiply the flour weight by this number.

Example: Flour: 100% (800-grams), Salt: 2%, IDY: 0.375%, Water 60%, Oil 2%

The sum is: 164.375% divided by 100 = 1.64375

Multiple flour weight by 1.64375. $800 \times 1.64375 = 1315\text{-grams}/1.315\text{-Kg}$.

If you want to put a dough formula based on weight measures into bakers percent. Flour is ALWAYS 100%.

Divide the weight of each ingredient by the weight of the flour and multiply by 100.

Example: 800-grams flour weight and 450-grams ingredient weight. 450 divided by 800 X 100 = 56.25% do this for each ingredient and you will have put your dough formula into bakers percent.

Ain't math great!

[Re: Percentages](#) **1052**

I'd suggest that you also post this on the PMQ web site (Think Tank).

<www.pmq.com>.

[Re: Switching from Grande cheese](#) **1053**

I agree with Craig, also the ADY should be activated in 100F water with just a small amount of sugar (actually, a pinch is sufficient), put the rest of it in the dough. What is the finished dough temperature? Ideally, it should be around 75F, if the dough is warmer than this it will further accelerate the rate of fermentation making matters even worse. Can you provide the weights for your salt, sugar and ADY as opposed to volumetric portions?

[Re: Starter with ADY trouble](#) **1054**

Don't worry about clostridium, the environment is too acidic, about the only thing to worry about is a change in the micro-flora resulting in a different flavor profile, if smells OK go ahead and proceed to activate it and make some dough with it, if the dough is OK and there is nothing strange about the flavor of the finished crust you're good to go.

[Re: Hidden dangers of old starters?](#) **1055**

A malted flour will always provide more crust color development with a fermented dough and since protein is a participant in the browning reaction the higher the protein content of the flour the more it will contribute to crust color development. It can safely be said that the impact of flour protein content is significantly less than that of a malted v/s non-malted flour, or inclusion of sugar in the dough formulation.

[Re: Diastatic malt vs sugar](#) **1056**

I was referencing the 20-grams of yeast in the dough formula shown so 80% of 20-grams would make it 16-grams in 4-Kg of flour or 8-grams in 2-kg. flour.

[Re: Dough Management Problem](#) **1057**

It wasn't in this thread was it? I think in that particular instance the individual had both flours and the KABF was more readily available, otherwise 100% of either flour would be just fine.

[Re: Diastatic malt vs sugar](#) **1058**

The rule is to allow at least 1.5 X the oven depth as free/open space in front of the oven for the oven tended to work in. Failure to do this typically leads to wishing you had.

[Re: Putting a Deck Oven in a Food Truck?](#) **1059**

The addition of sugar in this case is for crust color, so if you are satisfied with the finished crust color continue using sugar as you are.

I also suggest that you get the balled dough into the cooler within 20-minutes from the time the dough is finished mixing.

Keep us posted on the results.

[**Re: Dough Management Problem 1060**](#)

Once you remove the dough balls from the cooler you will need to allow them to warm to an internal temperature of 50F/10C (about 90-minutes) before opening them into skins, once the dough balls reach 50F/10C they will remain good to use for up to 3-hours at room temperature. Any dough balls not used in that period of time should be slightly flattened, placed on a lightly floured pan, covered to prevent drying (or you can place back into the dough box), then remove them from the cooler and allow to warm for only 30-minutes before you open them into skins.

[**Re: Big amount of recipes 1061**](#)

Using that kind of water temperature the dough was very warm and most likely over fermented becoming what is commonly referred to as "bucky". This is a condition where the dough is VERY elastic and difficult to impossible to open into a skin without the dough tearing.

Try making the dough again but use only 70F water. Use only a very small amount of water at 100F to hydrate the IDY in.

[**Re: Rubber band dough 1062**](#)

Fahrenheit (F).

[**Re: Diastatic malt vs sugar 1063**](#)

If you are in a restaurant you will have access to a cooler? Why not just stagger the times that you remove dough balls from the cooler so as to have a continuous supply of dough balls to work with during the entire 12-hour day?

I'm not sure I can help you with a dough that is fermented for 16-hours at ambient and then still be able to provide a consistent quality pizza over an additional 12-hour period of time during which the pizzas will be made. A lot of changes can/will take place in a yeast leavened dough over that 12-hour period at ambient.

[**Re: Big amount of recipes 1064**](#)

The next time you make it try making one with sliced fresh (RIPE) tomato rather than sauce, it really makes the red pop and contrast with the white and green.

If you can't get fresh ripe tomatoes try Stanislaus 74/40 Tomato Filets (drained for 20-minutes), they're superb!

[**Re: First Margherita 1065**](#)

Too hot for sugar in the crust!

[**Re: Diastatic malt vs sugar 1066**](#)

We did a study on herbs as it pertains to the flavor of pizza some years ago and what we found was very interesting. Oregano (dried) is the most over used herb on pizza, it also has the most dominant and identifying flavor, and is also responsible for the heart burn many older individuals complain about after eating pizza. In an effort to increase the flavor of their pizzas many operators just keep pouring on the dried oregano, then in short order they begin asking if anyone else has noticed the lack of flavor in the mozzarella cheese lately. Our tests showed that the dried oregano was over powering the delicate flavor of the cheese (mozzarella cheese by definition has a VERY mild flavor). We also found that our sensory panelists consistently associated the basil flavor with pizza. We then looked at the difference between fresh and dried basil. The fresh oregano (micro-leaf) was consistently preferred over the dried oregano by our panelists and when presented to

individuals who limited their consumption of pizza due to the heart burn issue they reported back to us that they didn't suffer the usual heartburn. At the time we were doing two major pizza shows a year so we presented our finding at the shows for two years in a row, the results were always the same, there was a much greater preference for fresh oregano over dried oregano and as a side study we began reducing the amount of cheese used on the pizzas in conjunction with the use of fresh oregano. We asked our audience what they thought of the pizza they were given (we did not prompt them in any way), the most frequently asked question was "What brand of cheese did you use?" "This pizza has a great cheese flavor". The pizzas were made using 3.75-ounces of shredded Grande WM mozzarella on a 12-inch pizza. The oregano used was fresh micro-leaf oregano adjusted to give a very mild but yet readily identified oregano flavor. The audience had a hard time believing that we got that level of cheese flavor from just 3.75-ounces of just mozzarella cheese. This led us back to our sensory panel for another look at dried oregano, we presented them with samples of pizza made with dried oregano at levels which were typical to that being used by the industry and then asked them to identify the flavor used in other pizza samples, what we found was that the dried oregano appeared to "wipe out"/over power their taste buds to the point where they were not able to readily distinguish different flavors which led us to think about the cheese comments as well as a growing trend in the industry to use ever increasing amounts of cheese to get a decent cheese flavor in the pizzas, it's not a change in the cheese, in my opinion, it's the excessive use of dried oregano that's at fault here.

[Re: Oregano before or after bake?1067](#)

Yes, omit the sugar, what temperature are you baking at?

[Re: Diastatic malt vs sugar 1068](#)

With short fermentation time the sucrose wins with longer fermentation time the diastatic malt powder wins.

[Re: Diastatic malt vs sugar 1069](#)

For IDY I would go with 0.4%, because the dough is mixed by hand it has to be hydrated by suspending it in a small amount of warm (100F) water before addition to the dough water. As for finished dough temperature I would suggest targeting 75F, which will put the dough water temperature at about 70F.

When I was teaching pizza making to local families I found that I could take almost any pizza dough formula and plug it into this procedure and get decent results, not spectacular, but everyone reported that it was an easy procedure to follow, didn't take a lot of attention (farm families have other things to do too) and always allowed them to make pizza as well as bread that their family really enjoyed. This is why I always revert to this procedure for someone just learning to make their first pizza, when you can sit at the table with your family and enjoy the fruits of your labor the incentive is pretty great to go on and make more and even better pizzas.
:chef:

[Re: Check my method please 1070](#)

Vertical wire tree racks are wire racks designed to hold pizza pans, screens and disks stacked vertically, some racks are designed to be free standing, like on a counter top while others are designed to be suspended from a wall, still others are constructed on wheels so as to be able to be easily moved about you can see these

if you Google "wire pan pizza support racks". If you go to American Metalcraft at <www.amnow.com> and search "Pizza Racks" you can see pictures of the free standing racks that many stores use.

[Re: Big amount of recipes 1071](#)

May I suggest an improved procedure?

Put water in mixing bowl first, add the yeast suspension, then add the salt and sugar immediately followed by the flour. Using a wooden spoon, mix the dough until it can no longer be mixed without fear of breaking the spoon, remove the spoon, add the oil and mix by hand until the oil is incorporated into the dough, turn the dough out of the bowl onto a lightly oiled surface, scrape the bowl clean and lightly oil it, knead the dough a few times (1 or 2-minutes), form into a ball and place back into the oiled bowl, lightly oil the top of the dough ball and cover with a piece of plastic (DO NOT SEAL OR COVER TIGHTLY), allow the dough to ferment at room temperature for about 3-hours, then turn the dough out of the bowl onto a floured surface and knead the dough for about 5-minutes or until it begins to look somewhat smooth. Lightly oil the bowl again and place the dough ball back into the bowl for 30-minutes, turn the dough out of the bowl and scale to desired weight pieces, form each piece into a ball, lightly oil each dough ball and place into individual plastic bread type bags (DO NOT USE ZIP LOCK BAGS), twist the open end of the bag into a pony tail and tuck it under the dough ball as you place it into the fridge. Allow dough balls to cold ferment in the fridge for 24 to 48-hours. To use, remove dough balls from fridge and allow to warm AT (NOT TO) room temperature until the internal dough ball temperature is in the 50 to 60F range (about 60 to 90-minutes, then roll the bag down around the dough ball and invert the bag over a floured surface allowing the dough ball to fall free from the bag, flour both sides of the dough ball and open into a skin by your preferred method. We have recently had discussion on this vert topic.

[Re: Check my method please 1072](#)

If you are referencing sucrose then the answer is sucrose.

[Re: Diastatic malt vs sugar 1073](#)

Sure, on the morning of the event open all of the dough balls into skins, place on pizza screens and store in a vertical wire tree rack(s) in the fridge, they will keep all day this way, to use just remove from the cooler 20-minutes prior to dressing and baking, turn off of the screen and re-stretch a little then dress to the order and bake. This is a similar method as used by many of the fast casual pizza places. You're still going to need a cooler of some type, as holding dough between 27 and 34C for what essentially amounts to all day is going to result in more than just a little change from the first to the last of the pizzas.

[Re: Big amount of recipes 1074](#)

When you remove the dough balls from the cooler BE SURE to allow them to warm to 50F/9.9C internal dough ball temperature (not higher than this), this will give you a full 3-hour window of time to open all of the dough balls into skins without too much/excessive difference in quality between the finished pizzas. This is what essentially all of the big U.S. box chains and a good many pizzerias do.

[Re: Big amount of recipes 1075](#)

You did well! Great lookin' pizza! :drool:

[Re: Made a few pies with Tom Lehman dough recipe in my home oven 1076](#)

No, none at all. Whole egg = 35% solids + 65% water, of the 35% solids about 12% is yolk which is 33% fat so the total fat being contributed by the whole egg is (10% (35% o 10% = 3.5% and 12% of 3.5% = 0.42% and 33% of 0.42% = 0.1386% total fat contribution in bakers percent from the 10% added whole eggs.

[Re: Delayed egg method](#) **1077**

I forgot to add that the salt level is 1.9% not 0.019% as indicated (76 divided by 4,000 X 100 = 1.9%) In view of the potentially weak dough you have it might be beneficial to increase the salt level to 2.5% (4000 X 2.5 (press the "%" key) and read the new salt weight in the display window. (100-grams is the new salt weight).

[Re: Dough Management Problem](#) **1078**

From what you have described and from the appearance of the dough balls, especially the last picture, I'm guessing that the dough is over fermented. Is there any chance that you can use it after 24-hours rather than 48-hours? The other option is to try reducing the yeast level 20-grams in 4Kg. of flour is 20 divided 4,000 X 100 = 0.5% Note: All of your percentages shown are incorrect. You don't say what kind of yeast you are using so I can't add anything more about the yeast except that you might try reducing it by 20% to see if that helps. Additionally, you say you are adding an "improver" can you provide a list of the ingredients in that improver, many times these improvers are a cocktail of ingredients, all of which may not be compatible with long fermentation times as they were designed and intended for use in bread formulas incorporating much shorter fermentation times, usually only just a couple of hours as opposed to days for a pizza dough.

[Re: Dough Management Problem](#) **1079**

Don't worry, that's perfectly normal. The dough will become smoother and stronger as it's worked and given more fermentation.

[Re: Torn dough surface question gt](#) **1080**

When we did our pizza seminars at AIB we told our students that proper attire was required of ALL persons in the shop. No open toe shoes, aprons or lab coats had to be worn, ALL jewelry that was worn and visible above the waist had to be removed (the rest we didn't want to know about) ;D regarding rings, a plain band was OK but if it was more than just a plain band it either had to be removed or covered with a plastic glove, everyone was also required to wear a hair net too and while on the topic of hair, if hair was worn below the collar it had to be restrained under the hair net (above the collar). It totally gives me the shivers when I see someone with unrestrained long hair working close to a mixer or a dough sheeter.

Regarding those TV personalities, don't you just love to watch them constantly wiping their hands on the towel they wear at their waist? It's a petri dish of bacteria! The mystery to me is why a chef's coat has a breast pocket or arm pocket designed to hold a pen or thermometer? It violates EVERY food safety rule in existence!

[Re: Jewelry and Food Preparation????](#) **1081**

Been there, done that many times!

Scenario:

I have four dough balls that are all under scaled/too light in weight and they are ready to be opened.

Corrective Action:

- 1) Determine how much additional weight has to be added to each dough ball.
- 2) Set aside one dough ball as a sacrificial dough ball which will be used to provide

the additional dough needed to bring the other three dough ball up to desired weight.

3) Cut a piece of dough from the sacrificial dough ball slightly larger/heavier than needed, using your scale trim the weight of the dough piece back to the target weight.

4) With MINIMAL handling add the trimmed dough piece to the bottom of one of the under weight dough balls (cut side facing the bottom of the dough ball) thus bringing it up to the desired weight.

5) When adding the trimmed dough piece just place it on the bottom (under) the dough ball, it will meld into the dough ball within a few minutes and nobody will be any the wiser of your error.

Note: The dough remaining as the sacrificial dough ball can be used to make a smaller pizza or it can be further subdivided to make bread sticks. If you plan on making another pizza from it cut the dough pieces from it around the sides of the dough ball thus retaining a somewhat round shape to it. Oh yes, those cut pieces that you trimmed off of the piece cut from the dough ball, just gather them up and place under the sacrificial dough ball, then open that dough ball last as this will allow more time for all of those scrap pieces to meld into the dough ball.

This was one of the things we used to demonstrate to our students in our pizza seminars.

Tip: A scissors is a great specialized tool for trimming those cut dough pieces to exact weight. Place the cut dough piece on the scale pan and cut to weight on the scale pan using the scissors, works like a charm! :chef:

[Re: How to combine/reportion dough balls after some cold ferment](#) **1082**

Does your mixer have a reverse spiral dough arm? If not sure please include a picture of it. If it does have a reverse spiral dough arm you will need to reduce the total dough size/weight which will allow you to mix the dough at a higher speed for improved development/mixing action.

[Re: Need help with biga dough](#) **1083**

It can/will both inhibit and prevent gluten development if added too soon. It prevents it by soaking into the flour before the flour hydrates, once the flour absorbs oil before water that portion of the flour which has become oil soaked cannot form gluten, we found that this is what led to everyone thinking that the weather influenced how much water the dough would absorb. This was when everyone was putting the water and oil in the bowl at the same time, the oil would float to the top of the water, then the flour was added and the oil soaked into a portion of the flour, this impacted how the dough felt (when more flour was oil soaked the dough felt soft (less gluten development) so flour was added to the dough, is less flour was oil soaked the dough felt firmer due to more gluten being developed sometimes leading to more water being added to the dough. This was blamed on the outside weather, now you know the truth, Mother Nature was found innocent. By using the delayed oil mixing method the flour is allowed to hydrate prior to the addition of the oil and dough consistency is restored.

[Re: purpose of oil](#) **1084**

Remember, change only one thing at a time!

[Re: Complications with dough management](#) **1085**

A higher dough absorption will make for a softer dough consistency which will expand even more in the bowl than your present dough, I thought that was what you were trying to control. If you want to add some tenderness to the finished crust

you can also add some fat to it.

[**Re: Complications with dough management 1086**](#)

Always remember though that those wonderful aromas coming from the oven while the pizzas are being baked will never be enjoyed by those eating the pizza, they are lost forever, it's only the less volatile aromas that the consumer gets to enjoy, sorta like comparing EVOO to Pomace grade olive oil. In the final end though you are absolutely correct, whatever YOU like the best is the way for YOU to go.

[**Re: Basil and olive oil 1087**](#)

Bags will be much better for this application.

A lower temperature will allow for a longer bake, a longer bake is conducive to a crispier crust as well as a crust that retains its crispiness.

Yes, if you bake at your proposed temperature or above 550F you will want to reduce or eliminate the added sugar.

[**Re: Help me with a hybrid dough 1088**](#)

Why more dough absorption?

[**Re: Complications with dough management 1089**](#)

Amen to that! When we love what we do it shows in our work. I'd rather spend 50-years doing what I love to do than 1-hour doing something that I don't like doing.

[**Re: When to add the oil 1090**](#)

I haven't see that for a long time now. Just something different to be sure.

[**Re: East Coasters Mock Chicago Square Cut Pizzas 1091**](#)

Your pizza looks great! :drool:

If you want to do some experimenting now you might try reducing the yeast level, maybe in 0.1% increments to see that improves the dough prior to opening (you indicated that it was getting big, but that's a pretty subjective term).

[**Re: Complications with dough management 1092**](#)

Doktah;

I'm not exactly sure what you mean in your second paragraph about re-ball the dough.

[**Re: Cold prove leading to loss of elasticity 1093**](#)

It sounds as if they might also be including the wheat germ too, if this is the case I would highly recommend keeping the flour refrigerated or frozen as germ oil will rancidify rather quickly. This can also be true for whole-wheat flours too.

[**Re: New pivetti flour 1094**](#)

Assuming you mean fresh basil leaves. Wilted they are great, charred, not so great, so I always put mine on IMMEDIATELY after removing the pizza from the oven and let the latent heat of the pizza wilt the basil and release the wonderful aroma, in some cases I may pull the pizza out but leave it on the peel, apply the basil leaves and put the pizza back in the oven holding it towards the top of the oven to quickly wilt the basil, then apply a drizzle of EVOO to the pizza, slice and serve.

With some more heavily topped pizza I've been known to add the basil leaves on top of the sauce so they are covered by the cheese and other toppings thus protecting them from the high oven heat.

[**Re: Basil and olive oil 1095**](#)

The procedure is very simple, immediately after mixing scale and ball the dough, lightly oil each dough ball and drop into individual plastic bread/bread type bags (DO NOT USE ZIP LOCK BAGS), pull the bag snug to the dough ball, twist the open end to form a pony tail and tuck the pony tail under the dough ball as you place it in the fridge. When ready to use, remove from fridge and allow to warm AT, repeat AT, NOT TO, room temperature until the internal ball temperature reaches 50 to 60F, then roll the bag down around the dough ball and invert it over a floured surface, the dough ball will fall free from the bag inverting the bag as it does so. Flour the entire dough ball and open by your preferred method. Used bags can be stored in a container or another bag in the fridge and reused many times if desired.

[Re: Cold fermenting in plastic bags. 1096](#)

Failure to cross-stack or allowing the dough to warm up to long after CF can also result in bubbles like that but those aren't too bad so I really wouldn't worry about them unless they were part of a bigger or different problem.

[Re: All Trumps High Gluten, bromated v unbromated dough diffs 1097](#)

No, I have not worked with that particular flour. I have never heard of a semi-whole-wheat flour. When the outer layer of the wheat berry is removed (that is what we call bran) the remainder is endosperm aka white flour after milling. There is such a thing as long extraction flour which contains a bit more bran as well as ash content but it is a long call from being "semi-whole-wheat".

Whole wheat flour contains roughly 20% bran, do you have any idea of the bran content of this flour? Since they say it contains bran it will require a higher dough absorption, my guess might be in the 70 to 72% range? To allow for hydration of the bran I would advise using an autolyse with this flour. Just all of the flour + all of the water, mix together and allow to hydrate for 1-hour, then add remainder of ingredients and mix together as a dough, be sure to mix it JUST until it starts to smooth out, DO NOT OVER MIX THE DOUGH as doughs containing high levels of bran do not tolerate over mixing well at all.

[Re: New pivetti flour 1098](#)

Peter;

It didn't used to be that way. I made a very good living when I went to work for Jewel Tea Bakery in Melrose Park, Illinois in 1962, by 1964 I had worked up to a line supervisor on the second shift and I was making about \$11,000.00 a year with full benefits. Like I said, today nobody really wants to work, much less go the extra effort so the baking industry has gravitated to the position that everyone is expendable and that position is now reflected in the pay scale. To give you an idea of how much that \$11,000.00 yearly income was, when I took my first position at the AIB in 1965 my salary was \$6,200.00 a year. During those first few years I went to night school and took every opportunity to learn as much as possible, I started my first group in 1967 and continued to grow it right up to the time when AIB made the move from Chicago to Manhattan, Kansas (1976/77). I continued to grow the Experimental Baking Group in Manhattan and finally split myself off from it to allow me time to teach classes and develop the Bakery Assistance activity which I was Director of when I finally retired 5-years ago.

In the end I can say that I was blessed with good decision making and a desire to succeed, I was rewarded with a job (I don't like to call it that, it was really participation in a very professional family of true experts in all subjects related to food and baking). I ALWAYS looked forward to the challenges each day would bring and I was rewarded well for my efforts. Here's a stat you don't hear much of,

during my nearly 50-years at AIB I only took 7 sick leave days, total! (I could have taken 14 each year). Four of those days were used when I got my pacemaker and three were used when I almost died from food poisoning in St. George, Utah. Granted, there were days when I probably should have stayed home but I didn't. Point is, most of us have the opportunity to make our lot in life, one just has to "work" to find it.

[Re: When to add the oil 1099](#)

Those bubbles are perfectly normal. When your flour has been over fermented it will begin to break down and become sticky, very extensible and oven spring will be reduced, after that it just keeps getting worse until you can pour the dough. No chance of reviving it either as the gluten has been severely degraded. You won't get any "off" flavors or aromas, just a more intense fermentation flavor and aroma which some might call "off". At some point you will get off flavors and aromas but that point will be after the dough breaks down and is unmanageable so it's kind of a moot issue.

Typically, the higher the protein content the more fermentation the dough will tolerate before breaking down (assuming U.S./Canadian flours).

[Re: All Trumps High Gluten, bromated v unbromated dough diffs 1100](#)

How about this;

50% Power Flour

50% KABF Flour

2% Salt

1% Sugar

0.375% IDY

62% Water (65F)

2% Oil

Mix just until smooth using delayed oil addition mixing method.

Immediately after mixing scale and ball.

Lightly oil dough balls and place into individual plastic bread type bags (follow normal procedure for cold fermenting in plastic bags).

Remove bagged dough balls from fridge about 90-minutes prior to opening into skins.

Roll bag down around dough ball, invert over a floured surface, flour dough ball on both sides and open into a skin.

Dress and bake.

Note: For a crispier pizza bake at 550F.

[Re: Help me with a hybrid dough 1101](#)

It sounds like your dad was the last of a breed, they don't make real bakers anymore. Those working in bakeries today are seldom, if ever educated in the trade, they're human robots just doing what they're told to do without any knowledge of why they're doing it. It used to be that when I went into a bakery and asked people how long they had been in the baking industry I'd get answers with two digits, now if I get two years I've found an "old timer", most are measured in months. Sadly, It's JUST a job anymore. Now with the closing of AIB there isn't anyplace for the baking industry to send people for formal training anymore either, and the price is being paid in high employee turnover just like many other industrial companies.

[Re: When to add the oil 1102](#)

The only time you proof the dough after opening it into a skin is if you want to make a thicker finished crust (like a thick crust pizza), otherwise, for a thin crust pizza you open the dough ball into a skin, dress it and bake it.

As to those high absorption doughs, they usually use an autolyse to help the flour absorb the water, they also require specialized handling (we recently had a good video here showing how it's done, maybe Peter can find it for you). Save those high absorption doughs for making AFTER you gain good proficiency making lower (60 to 65%) absorption doughs for now. As for opening the dough while still cold, I can't say if that will work for you or not, you will need to try it to find what works best for YOU with YOUR dough made with YOUR dough management procedure.

[Re: Cold prove leading to loss of elasticity](#) **1103**

Mike;

Yes, to the best of my knowledge, bromated flour is still the flour of choice in NY and NJ pizzerias. Bromate (a carcinogen) is converted to bromide (not a carcinogen) during the baking process and as long as the residual bromate is at 20ppb (parts per billion) or less it is deemed to be safe. At one time (back in the 60's and early 70's it was thought that all of the bromate was converted to bromide during the baking process as tests of the time couldn't detect levels as low as 20-ppb. The Japanese developed a test that could detect such low levels and the newspaper headlines were "Bromate found in baked bread" OMG! We're all going to die of cancer! The amounts being detected were in the single digit ppb range. Because of this bromate was taken off of the approved food ingredient list in many countries. The truth is that the air you breathe or the water you drink is more dangerous than the small amount of bromate residual in bread products. The U.S. set a limit of 20-ppb for residual bromate with a maximum limit of 50-ppm in bromated flour. Most bromated flours made today incorporate bromate at less than 15-ppm (BUT it COULD be as high as 50-ppm). At the commonly accepted <15-ppm level you probably won't see much difference in flour performance until you really begin to stress the flour out at around 4 to 5-days (CF) or 2 to 3-days RF. NOW, if the level used is higher, all bets are off the table as bromate is a VERY EFFECTIVE DOUGH STRENGTHENER. As for flavor, the tests that we did at AIB many years ago showed no impact on finished product flavor until the bromate level exceeded 75-ppm. As for crumb structure, bromate tends to promote a closer/tighter crumb structure, especially at higher levels >20-ppm. Unless the dough is subjected to very long fermentation times or the flour is weak or a composite flour (multi-grain) bromate levels much above 40-ppm will restrict dough expansion during baking leading to a condition known as "scalping" in white pan bread production where the top crust separates from the loaf and is then pulled off at the vacuum depanner.

We used to refer to bromate as a "crutch", it was seldom ever really needed and it was used more as a precautionary measure than as an essential ingredient, with the consumer health safety concerns over potassium bromate new dough strengtheners were developed aka bromate replacers, these for all practical purposes, are just as effective as bromate but without any of the health safety implications associated with bromate and are commonly used today to help strengthen otherwise weak or highly stressed doughs.

Probably more than you wanted to know.

[Re: All Trumps High Gluten, bromated v unbromated dough diffs](#) **1104**

Absolutely! This is why I encourage those not as skilled at opening a dough ball to open the dough at a colder temperature. Also, the type of flour can have a great impact, a weak flour may be very soft and extensible at anything but a cold

temperature, but for most folks, using a "typical" U.S. pizza type/bread type flour, a cold dough right out of the fridge will be excessively tough and elastic to open easily, in addition, there is also a possibility that the dough will be cold as it goes into the oven which dramatically increases the probability of severe bubbling or in some cases taking on more of the appearance of pita than pizza in the oven. :(

[**Re: Cold prove leading to loss of elasticity 1105**](#)

By "cross-stacking" you will also prevent the development of excessive condensation in the individual containers which results in a wet dough. The biggest benefit to cross-stacking is that it is conducive to achieving a consistent fermentation rate which results in more consistent finished dough performance.

[**Re: Cold prove leading to loss of elasticity 1106**](#)

Here is what I'm suggesting:

Lightly oil each dough piece as you place it into the individual dough boxes, leave the box(es) open until the internal dough ball temperature reaches 50F, then lid the boxes for the duration of cold fermentation. When you want to use the dough, remove from the fridge and KEEP COVERED/LIDDED, allow the dough to set AT room temperature until the internal dough ball temperature rises to 50 to 60F (anything in that temperature range will work OK), then remove the dough from the container and proceed to open into a skin by your usual manner. DO NOT RE-BALL the dough.

[**Re: Cold prove leading to loss of elasticity 1107**](#)

Unless you're making bread, ditch the "window pane" test for gluten development, instead, just mix until the dough "just" takes on a smooth appearance. Your mixer will think kindly of you and you will get a finished crust with a more open crumb structure with better bake-out properties. You don't mention anything about your finished dough temperature or how you are cold fermenting your dough, but you should be looking for a finished dough temperature in the 70 to 75F range and either cross-stacking/leaving containers open until dough reaches 50F internal dough ball temperature or plastic bagging (preferred). Failure to do any of these can lead to a weak dough condition, especially after 3 to 5-days in the fridge. Also, you don't mention which "00" flour you are using but do be aware that some of the Caputo flours are not designed for more than about 12-hours of fermentation time while others are designed for longer fermentation times and might be better suited to your application.

More information would be helpful.

[**Re: Cold prove leading to loss of elasticity 1108**](#)

In your dough formula, what type of yeast are you using and how are you adding it.

[**Re: All Trumps Unbromated/Unbleached - Inconsistencies? 1109**](#)

Which A.T. flour are you using: #50143; #50121; or #50111?

[**Re: All Trumps Unbromated/Unbleached - Inconsistencies? 1110**](#)

No, DO NOT EVER vacuum package pizza crusts or tortillas! Both are prone to clostridium which can be (usually is) deadly. There is a track record for clostridium growth in tortillas (two cases that I'm aware of) out of Canada. Gas flush packaging uses either carbon dioxide or nitrogen with about 0.5% oxygen to prevent growth of clostridium. The material you are thinking of is a marine colloid such as Xanthan or Carageenan gum for increasing moisture retention in baked products. Balchem is a company specializing in these ingredients and they have a product that they

call Ticaloid Lite which I've personally used in this application and it works very well.

[Re: Different Stages of a Par Baked Crust](#) **1111**

Mo;

The shelf life of par-baked pizza crusts stored at ambient room temperature (70 to 85F) will depend to some extent upon the method by which it was made (the dough that is). A crust that was made from a dough that was cold fermented for 24 to 48-hours will typically have a shelf life of about 4-days before mold rears its ugly head, if the fermentation period is more along the lines of 5-days you can add another 12 to 24-hours to this but if it was made using a sourdough method where the pH of the finished crust is down around 4.2 or lower you might get an additional 2 to 3-days (possibly more). With refrigerated storage (34 to 38F) it's entirely possible to double these numbers and with frozen storage mold is no longer the issue, instead we are now concerned over things such as oxidative rancidity, freezer burn (a MAJOR issue in home freezers with automatic defrost cycles), with frozen storage periods of more than 45-days there can also be oxidative flavor changes which can render the crust bland/tasteless, even when reheated. In most home freezers with auto defrost we see moisture migration from the crust (freezer burn) within the first two to 3-weeks with it becoming progressively worse as time progresses. By the time the crust has been in the freezer for 60-days or less it is so bad that the crust warps and checks or cracks, because of these potential issues with frozen storage we don't recommend storing crusts or other yeast leavened baked foods for that matter, more than 3 to 4-weeks.

Note:

With the above cited mold issues the appearance of mold will also be influenced by the level of inoculation/amount of exposure to mold.

The issues related to frozen storage are largely related to the crust temperature at time of freezing, the rate at which the crust is frozen and the characteristics of the packaging material used to package the crusts in. Commercial manufacturers also use a gas flush packaging to address the oxidative issues.

[Re: Different Stages of a Par Baked Crust](#) **1112**

Try this;

DO NOT brush the skin with oil, instead just brush the bottom and two side edges with water, then apply your filling, fold the top half of the skin down over the bottom half aligning the edges, crimp the edges using finger pressure, transfer the calzones to a baking sheet, cut or tear a vent hole in each calzone, brush with melted butter and bake at 450/ 232C until golden brown. Because of the moisture content of the fillings calzones do not fry well at all. The only exception to this is when the calzones are fried and then finished in the oven.

[Re: Sauce filled calzone problem](#) **1113**

Peter;

Your second reference is EXCELLENT! That's a good one for the "LIBRARY".
You never fail!

[Re: adding yeast to dough, does order really matter?](#) **1114**

What you will get will most likely be more like a thin crispy style of pizza, go ahead and do it, I promise you nothing bad will come of it and it will serve as a learning experience for you too.

[Re: Can I swap out a dough for a different type of pizza](#) **1115**

Agreed, with small amounts of dough it matters not.

[Re: Bulk ferment in big ball or unshaped? 1116](#)

Sourdough starters are not yeast based, instead they are bacteria based and we all know, or should know how rapidly bacteria can multiply under a myriad of conditions. Yeast requires a lot of oxygen to get it to reproduce but once you get it reproducing it multiplies very fast.

[Re: adding yeast to dough, does order really matter? 1117](#)

Thank you for the picture, those aren't the tiny bubbles I was at first thinking of but those are the result of baking at a very high temperature, above 850F.

[Re: Tiny Bubbles on the crust 1118](#)

Hummm, I must have been side tracked, didn't know you were looking for second level dough formulas.

You might give this one a try:

Flour: 100% (Strong bread type flour)

Salt: 1.75%

Sugar: 2% (optional)

Oil: 2%

IDY: 0.375%

Water: 62% (70F/approx.)

Target finished dough temperature: 75 to 80F

Procedure:

- 1) Put water in mixing bowl.
- 2) Add salt and sugar (if used).
- 3) Add flour then add the IDY on top of the flour.
- 4) Mix at low speed just until you don't see any dry flour in the bottom of the mixing bowl.
- 5) Add the oil and mix another minute at low speed.
- 6) Mix at the highest speed possible just until the dough takes on a smooth appearance.
- 7) Take the dough directly to the bench for scaling and balling.
- 8) Lightly oil each dough ball and place into individual plastic bread type bags (NOT Zip Lock type bags).
- 9) Twist the open end into a pony tail to close and tuck it under the dough ball as you place it into the cooler/fridge.
- 10) Allow the dough to cold ferment for a minimum of 24-hours (48-hours is the "sweet spot") but dough can CF for 72-hours.
- 11) Remove dough ball(s) from fridge and allow to warm AT room temperature until the internal temperature reaches 50 to 60F.
- 12) Roll bag down around the dough ball and invert over a floured surface allowing the dough ball to fall free from the bag.
- 13) Flour both sides of the dough and open into a skin by your preferred method.
- 14) The pizzas can be baked on a stone, steel or in a pan/disk.
- 15) Baking temperature in a home oven is 500F.

Many readers here have used this dough formula and procedure with good success. The formula and procedure are designed to mimic that used by many pizzerias as well as some of the larger pizza chains. Once mastered, it can be modified to provide whatever characteristics you desire in your finished pizzas.

[Re: Newbie looking for a basic beginner recipe for home oven 1119](#)

Almost NONE of the yeast cells reproduce during dough fermentation, if they did we would have what is known as run away fermentation, think of it like a nuclear explosion of yeast cells, 1 becomes 2, 2 becomes 4, 4 becomes 8, 8 becomes 16, 16 becomes 32, you see the trend. Yeast cells divide by a process known as budding, within the yeast that we add there are mature cells as well as budded cells (cells partially budded with "daughter cells") as well as recently divided cells. During the fermentation process the mature cells DO NOT bud, some of the already budded cells will mature and divide but neither will reproduce, the recently budded cells may mature but they will not reproduce. Any damage done to the yeast cells due to improper hydrating will actually impact the number of cells capable of participating in what we call fermentation.

[Re: adding yeast to dough, does order really matter? 1120](#)

If you will go to the PMQ web site at <www.pmq.com> and go to the Recipe Bank, and use "pizza dough" for your search words you will find a home made pizza dough "recipe" that I have posted there. This is a well proven dough formula and procedure and will serve to get you started making pizzas from which you can build upon.

[Re: Newbie looking for a basic beginner recipe for home oven 1121](#)

Give it a try and let's see how it works out for you.

[Re: Complications with dough management 1122](#)

I see your problem already. A 10 to 20-minute rest (fermentation period) after mixing is WWAAYY too short. Change your 10 to 20-minutes to 2-hours (or more) and I think you will find you will get a smoother dough. You need to allow time for biochemical gluten development to develop some of the gluten before the kneading process, or if you want to develop biceps like the village blacksmith you can develop the gluten through energy input (like a mechanical dough mixer does) but it will take an hour or more of continuous dough kneading to do so. I don't know about you but my biceps are just fine and I've got better things to do with my time so I always opt to let biochemical gluten development do the hard work of gluten development for me, allowing me to save my strength for dressing, baking and eating those pizzas :-D

[Re: Complications with dough management 1123](#)

Scott;

Once the IDY has been hydrated or the ADY has been hydrated and activated either one can be added directly into cold water without any problem (remember, it's the hydration process that causes the problems here), once hydrated they are both just like compressed yeast/CY.

Compressed yeast/CY, since it is already hydrated, can be put directly into cold water without any problems at all.

Note:

ADY takes about 10-minutes to fully hydrate, during that time it will also activate. IDY only takes about 3 to 5-minutes to fully hydrate so you will not see any activation during that time. This is why we say that ADY is both hydrated and activated prior to addition but IDY only needs to be suspended. When the IDY is added in this manner its performance is essentially identical to that of CY, however if you are replacing ADY with IDY you might want to both hydrate and activate the IDY prior to addition to retain the same performance/fermentation characteristics. This is really not much of an issue with regular doughs but it can be an issue with very short time doughs such as no-time dough or emergency dough.

[Re: adding yeast to dough, does order really matter? 1124](#)

You will want to use a dial aka stem type thermometer to measure the internal dough ball temperature. Yes, a cold dough can/will promote sticking to the peel as a small amount of condensation can form at the interface of the peel and the dough while the skin is being dressed. If your dough is still lumpy/knotty after kneading it sounds as if you may not be kneading the dough enough, yes, this can result in holes in the skin during opening. Cold dough is definitely harder to open than warm dough. As for your dough weight, it's actually a little more than what I personally use for a 10" skin, I use 7-ounces/roughly 200-grams.

[Re: Complications with dough management 1125](#)

The "I" in IDY stands for INSTANT as in instant hydrating (actually just fast/rapid hydrating), so if you put the IDY in cold water the water will enter into the yeast cells and remove the glutathione from the cells before the cell walls can swell to seal in the glutathione. The 100F water promotes rapid swelling of the cell wall to limit loss of glutathione from the yeast cell(s). When glutathione is flushed from the cells the yeast isn't killed but its ability to ferment is seriously impaired PLUS glutathione is a serious reducing agent which will make a dough soft and extensible to the point where it's difficult to handle (think "dead yeast" which is used as a more consumer friendly form of L-cysteine/PZ-44).

[Re: adding yeast to dough, does order really matter? 1126](#)

Allow the boxes to remain cross-stacked until the internal dough ball temperature reaches 50 to 55F. If targeting a 3-day C.F. you can go with 55F but if targeting a longer C.F. go with 50F. Once the targeted dough ball temperature is reached you can apply the lid/down-stack. After the C.F. period remove the box from the cooler and place at room temperature and allow the dough to warm to 50F but not more than 60F (internal temperature) before using the dough. Note: Most pizzerias use 50F as it allows for a longer window of time to use the dough. One other thing, be sure to lightly oil the top of the dough balls as you place the box in the cooler, this will prevent excessive drying of the dough during the cross-stack period. DO NOT oil the box.

[Re: Doughmate Dough Trays 1127](#)

First of, after the CF period you should allow the dough to warm to 50 to 60F (internal dough ball temperature, NOT external). Since you are getting a lot of sweating in the fermentation containers I'm guessing that your finished dough temperature might be excessively high, you don't mention what it is but I'd suggest targeting 70 to 75F for the finished dough temperature (after mixing). As you are having some issues with opening the dough I'd also suggest reducing the dough absorption from your present 66% to possibly 62% as this will make the dough easier to handle both during opening and on the peel, then as you become more proficient you can begin to increase the absorption incrementally (66% may be too high for your specific flour, dough management procedure or skill level).

Remember that the ideal absorption is that which provides the best dough handling properties for YOU. It is NOT recommended that you oil your wood peel, this only makes the dough more difficult to slide off, instead, just use it as it is after lightly sanding and NEVER wash a wood peel, just wipe it down with a damp towel. Lastly, you don't say what the dough weight is for the size pizza you are making so we can't determine if your dough weight is correct or not. If you are not using sufficient dough weight you might be stretching the skin too thin which will significantly increase the tendency for the skin to adhere or exhibit poor release

properties from the peel.

[Re: Complications with dough management](#) **1128**

For cinnamon rolls we want a sweet tasting roll not necessarily a well fermented flavor so for this reason I normally like to target a finished dough temperature between 70 and 75F/21.1 and 23.9C, in some cases I will target a finished dough temperature of 80F/26.7C and ferment the dough at room temperature for only 2 to 3-hours before using it to make my cinnamon rolls.

The reason why I am A.R. on temperature is because it is the temperature of the dough that drives fermentation and as I've always said "Without temperature control you cannot have effective dough management" Without effective dough management you cannot have consistency from one dough to the next.

By far, the best way to judge a pizza dough to determine if it has been sufficient mixed is by its appearance. If you stop your mixer after each minute of mixing you will be able to see the dough progressively becoming smoother. As soon as the dough has taken on a smooth (not lumpy) appearance, it has been sufficiently mixed. With just a little time you will be able to look at the dough as it is mixing and see it take on the desired smoothness, once you see that, you're done mixing. As a rule, with pizza doughs as well as pastry doughs it is better to error on the under mixed side of the equation than to over mix the dough. The reason for under mixing a pastry dough is because it will receive significant gluten development during the following rolling and/or folding/forming procedures.

It is impossible to answer your question regarding your mixer as all mixers are different but suffice it to say that low speed should only be used to combine the ingredients together prior to mixing the dough at a higher speed where gluten development will actually take place, with most home type mixers I'm guessing that this will be either speed #2 or #3 but in the end it will be the highest speed at which the mixer will mix the dough without showing strain or overheating the motor.

If you don't have a spiral design dough arm on your mixer you will most likely need to periodically stop the mixer to pull the dough down off of the top of the "C" hook aka "J" hook. If your mixer has a spiral design dough arm you will not need to do this as the design of the arm pushes the dough down to the bottom of the bowl rather than allowing it to climb up the hook.

[Re: Cinnamon rolls](#) **1129**

And I remember very well back in the late 1970's and early 80's when Chicago pizza patrons were sending pizzas back to the kitchen from some of the new pizza places because the pizzas were "burnt". It was kind of a culinary shock to Chicagoans that anyone would actually eat a burnt pizza! One has to remember that it's the huge amount of variation/difference between pizzas made in different regions, even cities and towns across this great country (and now you can add "the world") that has driven pizza to the pinnacle of culinary enjoyment that it has achieved. All of the things that make those pizzas different are the very things that have driven and continue to drive the popularity of pizza. Long Live Pizza!

[Re: East Coasters Mock Chicago Square Cut Pizzas](#) **1130**

For bulk fermentation it is generally considered better to use a fermentation container that is smaller in diameter and deeper in depth than a rectangular shaped shallow box. The reason for this is because the smaller diameter X deeper container allows less surface area for evaporative cooling and drying which means the dough ferments at a more constant rate (as a bulk dough) ASSUMING WE ARE TALKING ABOUT A REAL "BULK" DOUGH SIZE. If you are referencing 20-ounces

of dough as a bulk dough for all practical purposes it is really nothing more than a large size dough ball and it acts as such during fermentation. For home bulk dough fermentation I've found that a pasta pot works extremely well when I'm fermenting several pounds of dough. Save the dough boxes for cold fermenting your dough balls (be sure to follow the cross-stack procedure) to avoid disappointment when you open the boxes to use the dough balls.

[**Re: Doughmate Dough Trays 1131**](#)

Not to worry, even though your dusting/bench flour might be malted the malt will not convert any starch to sugar as there is not sufficient time for that to happen when used as a dusting flour.

[**Re: Using all purpose flour when shaping dough 1132**](#)

JD;

Well, it all depends if you are mixing your dough by hand or using a mechanical mixing device. If you are mixing the dough by hand the IDY must be suspended in warm (100F) water prior to addition. The best way is to add it to the dough water in the mixing bowl, however, if you are using a mechanical mixing device where the total mixing time will be 5-minutes or more the preferred way to add the IDY is to just add it (dry) right on top of the flour when you begin mixing. If the total mixing time will be less than 5-minutes it is recommended that the IDY be first suspended in 100F water and mixed into the dough water prior to beginning the mixing process.

[**Re: adding yeast to dough, does order really matter? 1133**](#)

If your dough rises and then collapses this is what is referred to in the bread making circles as the first full rise which represents about 60% of the total amount of fermentation the flour used in the dough will tolerate before complete break down. In a case like that all you need to do is to re-ball the dough and wait for the dough balls to ferment sufficient to be opened into skins, which depending upon temperature, amount of yeast, amount of salt and flour strength can take anything from 90-minutes to several hours.

[**Re: Over fermentation issues \(CY or Flour issue?\) 1134**](#)

Your dad should have known Don Kinstrand?

[**Re: When to add the oil 1135**](#)

Bruce;

Welcome to the site!

The next time you make your N.Y. style pizza take some pictures, top, bottom, and a cut slice showing the internal crumb structure and send it over with a list of what you like and dislike about the pizza, also be sure to give us your dough formula as well as the entire dough management procedure including all temperatures and times. Baking conditions will also help. With this information there are many of us here who can help you achieve the characteristics you are trying to get in your pizza. You might go to my web site <www.doughdoctor.com> and view some of the videos I have posted there on making New York style pizza.

[**Re: Living in Japan forces the necessity to learn to make NY Pizza 1136**](#)

John;

From the looks of the pizzas in your pictures I'd say your pizzas are somewhat thicker than a typical New York pizza, however it's YOUR pizza and YOUR version of a New York pizza so it is what it is. If your customers like it....go for it. Case in

point, we have AJ's New York Pizza, Google: AJ's New York Pizza, Manhattan, Kansas. As the name indicates we sell a New York style pizza (by the slice) but the pizza is different from a true New York slice in that it is crispy (more of a New Haven style pizza), so crispy that one can pick a slice up by holding just the edge (something you could NEVER do with a true New York slice) but yet people just love it (five awards for best pizza in 10-years) and three stores, so Adam is doing something right. You HAVE to play to the preferences of YOUR audience! A true N.Y. slice would never sell here as it is much too soft, so we made it crispy and people HERE love it. If 700 or 750 grams of dough works for whatever size you are making and people like it.....go for it!!!! Never over think success, just accept it.

[Re: 20" \(50cm Pies\) im up to 24oz \(700g\) dough balls to get up to size 1137](#)

But puff pastry dough doesn't contain any yeast.

[Re: Blitz Pastry method? 1138](#)

Rolls is correct with the name of the butter "LURPAK". I am sure that there are other butter brands that will work equally as well. You want to have a butter that will NOT be incorporated into the dough during mixing, shredded butter should work OK if it is a coarse shred. As for dough absorption I think 50% is too low, I'd go with 55% or a little more. If you cut the finished dough with a sharp knife you MUST be able to see the pieces of intact butter in the dough. The larger the pieces of butter the more predominant the flake will be.

[Re: Blitz Pastry method? 1139](#)

Dough that is opened and used at a temperature under 50F exhibits a strong propensity to bubble during baking and dough that is much above 60F is beginning to ferment at a faster rate so it is becoming increasingly gassy which can also result in large bubbles in the finished crust as well as the fact that the dough as it ferments becomes increasingly more difficult to open and shape into a pizza skin.

[Re: Dough ball questions 1140](#)

Actually, after you take the dough out of the fridge you are not proofing it, instead you are tempering it. The ideal temperature to allow the dough ball to come to before you begin opening it into a skin is in the 50 to 60F range. As a newbie you may not be very proficient at opening the dough so you may find it a bit easier to open the lower end of the temperature range (50 to 55F), remember, this is the INTERNAL dough ball temperature so you will need to have a dial aka stem type thermometer to measure the temperature.

[Re: Dough ball questions 1141](#)

When we did the work on gas v/s electric ovens we had identical ovens of gas and electric. There was a Blodgette deck (gas and electric as well as an XLT (gas and electric) and the gas always gave a faster bake. We even went so far as to work with XLT to modify the electric air impingement oven to see if we could get it on par with its gas counterpart, we changed finger configurations to and bottom and worked with the fan speed then replaced the fan with new ones having moving more air, when all the dust had settled we couldn't get the electric oven to bake the same as the gas oven.

[Re: Opening a NY Style Sliceshop 1142](#)

Most shops will use a separate oven for reheating since the oven will be opened constantly as slices are reheated. Also, it's not very efficient to have the oven reheating the slices "out back" in the kitchen. Most shops have it right in front of

the customer. Remember, the reheat time will likely only be a minute or so.

[Re: Opening a NY Style Sliceshop](#) **1143**

Your idea is sound but your timing is off, instead of pouring the water when you place the pizza in the oven you should do it several minutes prior to placing the pizza in the oven. You should not be trying to flood the oven with steam as you would when making certain types of breads, instead you just want to add a little moisture/humidity to the oven. The amount of water added needs to be measured so it is all evaporated at about the same time the pizza is done baking. I'm not sure the use of lava rocks is the best idea either as it increases the surface area for evaporation which puts a lot of moisture in the oven all at once (this is called "flooding" the oven with steam, instead you want as little area for surface evaporation as possible. Think a 2" diameter piece of pipe, 6-inches long (automotive tailpipe comes to mind) with a flat piece of steel welded to one end so it will hold water and stand upright in the oven, experiment with the amount of water added to the pipe. The issue that you will need to work out is when you add the water to the pipe it will be very hot thus releasing steam rapidly into the oven (not what you are looking for). Maybe pour boiling water into the room temperature pipe and place it into the oven a minute or so prior to placing the pizza in the oven would work better? Like I said, this will be the challenge.

[Re: Humidity in oven](#) **1144**

Hang with us and you'll be making great pizzas in short order. Parallei's advice is spot-on. I have a Dough Management Procedure posted here that you might try, it's easy to follow and makes a good pizza too, then once you have mastered that you can begin experimenting with variations to the formula or dough management procedure to satisfy your curiosity or make a pizza that is more specific to your likes.

The most important thing is to have fun of your pizza journey!

[Re: Joe Heffernan/The Independent, Seattle/ChefSteps dough recipe](#) **1145**

Your assumptions about refrigerating the dough are absolutely correct. In addition to allowing the dough to be held for days rather than hours it also provides for much improved dough consistency and financial return, just ask Papa John's if it's any cheaper to provide refrigerated dough from a commissary once a week as opposed to making fresh dough every day at each store.

[Re: Are American Pizzas \(New York etc\) made with hard or soft wheat?](#) **1146**

Optimum dough fermentation for a straight dough is best defined as first full rise + 25% of first full rise time. However since the straight dough procedure is seldom used when making pizza and instead a hybrid procedure is more commonly used employing different fermentation conditions there is no hard and fast rule for determining optimum fermentation, the best definition I can give you is optimum fermentation is that fermentation time which provides the best overall dough handling properties at the time of opening the dough balls into skins by whatever method you opt to use. Forget bread dough technology, it doesn't apply to pizza dough. The only real way to determine optimum fermentation is through experimenting under CONTROLLED conditions, this means that you will need to strive to maintain those factors which affect the fermentation rate as a constant, think finished dough temperature, dough absorption, type, amount and freshness of the yeast, room temperature, refrigeration temperature, internal dough ball temperature at the time of opening (50 to 60F). In other words, Effective Dough Management.

[Re: Pizza aerobics](#) **1147**

I can't say much about your dough process as you don't include the finished dough temperature, but I can say that 20-minutes for the dough to warm to 50 to 60F (NOT ROOM TEMPERATURE) is mmuucchh too short, instead use a thermometer to measure the internal dough ball temperature to determine the time for your specific conditions.

To replace your bread flour with Caputo "00" flour is totally possible but I would advise you to select a flour with a long fermentation tolerance if you plan on following your present procedure. Any oven that will bake at 700F or higher will handle the "00" flours just fine.

Also, be aware that all flours are different so you may need to adjust the dough absorption with the new flour.

[Re: Joe Heffernan/The Independent, Seattle/ChefSteps dough recipe](#) **1148**

A biga is nothing more than a pre-ferment for use when making dough. In the baking industry a plastic biga is referred to as a "sponge" to be used with the sponge and dough process of making bread, if the biga has sufficient water to make it a liquid it is referred to as a brew in the baking industry. The purpose of these is to condition the gluten in a portion of the flour and to develop a level of flavor through fermentation in that flour.

A biga will usually contain from 30 to 50% (though sometimes more) of the total formula flour with an absorption of between 50 and 60% (again, it can be greater than this).

The fermentation time for a biga is usually in the 12 to 24-hour range with yeast levels (as compressed yeast, though any type of yeast can be used at correct substitution levels) of 1% for the shorter times and 0.25% for the longer time, but this should only be used as a guide as the amount can/will change with factors such as flour strength and temperature in the fermentation area.

To start a biga place the water (75F) in an appropriate size container, add the yeast and stir to suspend the yeast, then add the flour and mix in until the flour has been fully hydrated, that's all the mixing that is required. Note the temperature of the biga as well as the room temperature. lightly cover the biga (I just drape a piece of plastic over the container) and allow to ferment for the desired time. Then transfer to a mixing bowl, add the remainder of the flour and the other ingredients as well as the water (cold/45F), mix the dough in your normal manner just until it takes on a smooth appearance. At this point some prefer to bulk ferment the dough, my own preference is to scale and ball it at this time, and cold ferment for 24-hours or allow the dough balls to ferment at room temperature for about 6-hours for use on the same day as the dough was mixed. You can adjust the amount of flour in the biga, the amount of yeast or the fermentation time to vary the flavor of the crust.

[Re: Biga - so many questions and so many things to learn!](#) **1149**

By us the code requires that ALL ovens be totally under a hood, gas, electric or otherwise! Best to check with your codes department AND be sure to get their opinion in WRITING prior to purchasing your oven/ovens. Gas ovens will exhibit superior and faster baking properties due to the higher concentration of moisture in the air within the baking chamber due to moisture/water being a byproduct of combustion, in an electric oven the air is much drier so heat transfer is not as good and baking/reheat times are longer (about 20%). If you opt to go electric be sure to get an estimate of operating cost from your local utility company. I'd still opt for a full size electric deck over a couple of the smaller ovens if space permitted.

[Re: Opening a NY Style Sliceshop](#) **1150**

While I can't prove it, my thoughts have always been that the Italian "00" flours probably contained a portion of U.S. or Canadian hard wheat to give it the longer fermentation tolerance that we see in some of the newer flours. I don't follow the Italian wheat varieties or the wheat breeding programs associated with developing their wheat so I have to plead total ignorance but I have seen what the breeders can and have done with U.S. wheat varieties so it wouldn't surprise me at all if they have developed soft wheat varieties with decent fermentation tolerance. To give you an example, wwaayy back in the 70's it was said that hard red winter wheat could not be developed with much more than about 16% protein content, the breeders proved that to be wrong, very wrong as then developed a couple of varieties with protein contents approaching 25%, yes! 25% protein content! I was able to test some of the flour from those super high protein content wheat varieties and boy were they ever STRONG! They were so strong that we couldn't over mix them in our mixers and fermentation tolerance was through the roof! Those characteristics were so diametrically opposed to what was desired that further work on those varieties was stopped and needless to say seed was never released for planting, no one wanted to run a risk of any of that stuff getting mixed into the normal HRW crop, and there was a fear that the DNA of the protein might be different too which could potentially open a Pandora's Box with all other wheat varieties. Moral of the story: Never challenge a wheat breeder, and never tell them that it can't be done!

[Re: Are American Pizzas \(New York etc\) made with hard or soft wheat? 1151](#)

I believe that I've mentioned this before that high absorption doughs are the one weakness of spiral mixers, they just don't handle them quite as well as planetary mixers do. Holding back a portion of the water is the only realistic way to mix high absorption doughs in a spiral mixer. When we did it we used to add 70% absorption to the dough right up front and then gradually add the remainder of the water after the dough was partially developed. This worked well for us too.

[Re: Need help with biga dough 1152](#)

In the U.S. as well as Canada durum wheat is a different type of wheat than the hard red wheats used for making strong flours. The durum wheat produces gluten that is very tough and elastic which is excellent for pasta production which is why we typically reserve durum for use in making pasta, it is also widely used in making oriental noodles. The types of wheat used for milling into flour for bread and roll production are varieties of hard red winter, hard red spring, or hard white wheat. We also have varieties of soft wheat which can be either soft red or soft white wheat varieties. The soft wheats are typically lower in gluten forming proteins which also produce a softer, more extensible gluten characteristic. In the U.S. and Canada soft wheat flours are reserved for use in making pastries, cookies and biscuits which is why they are referred to as "pastry flours".

[Re: Are American Pizzas \(New York etc\) made with hard or soft wheat? 1153](#)

A huge risk that is run by following the above "edit" note is that of washing (separating) the gluten from the starch (this is how we "wash" gluten from the flour). If the gluten is even partially separated from the flour it is impossible to re-incorporate it thoroughly and the end result is a dough that has a lumpy appearance which is somewhat weaker too. We ran into this very issue in the bread and bun industry when using the brew process (essentially a biga) where the gluten would be separated during agitation (only 1-r.p.m. sweep agitation) resulting in dough weakness, this eventually lead to the industry, for the most part

reverting back to the sponge and dough process (the sponge is essentially a 50 to 55% absorption biga) which after the fermentation period is placed into the mixer and mixed with all of the other ingredients at the same time to produce the desired dough characteristics.

[Re: Need help with biga dough 1154](#)

Why not just place a full size deck oven right behind the counter, you will have greater capacity, more consistent temperature and in my opinion it will look more "professional". I've seen this done many times with great success.

By the way, Marsall deck ovens would be a an option to look at for this application as they have a thick deck for storing a lot of latent heat which you will need for quick reheating of the slices. I'd also go with gas if at all possible, as it's much more efficient and actually gives a better bake.

[Re: Opening a NY Style Sliceshop 1155](#)

However, if you are asking about how the factors involved in making dough for consumption which can be tossed as seen in the video, the factors are:

2 to 2.5% salt.

Flour with a high protein content.

Optimum dough absorption, NOT MAXIMUM, probably in the 58 to 60% range.

Optimum dough fermentation for the yeast level employed.

It is interesting to note that in the video we see the dough balls being partially opened using a pastry pin prior to hand tossing, this is important as it provides a more uniform thickness dough skin, without thin spots, which makes it MUCH easier to toss without tearing. You have heard me advocate this many times for those who might be "toss challenged".

The real key here is to mix the dough just until it develops a smooth appearance and then allow biochemical gluten development to develop the gluten for you. This results in a strong and extensible gluten structure as opposed to mixing which develops a more elastic gluten structure.

[Re: Pizza aerobics 1156](#)

The dough looks like it can take another 2 to 3-minutes of mixing, but what you have is indeed much improved.

[Re: Need help with biga dough 1157](#)

That metal clicking, like "tink, tink, tink" is the agitator hitting the bottom of the bowl. With the bowl in the fully raised position run the mixer through each of the gears, if you get the same tinking sound you will need to adjust the bowl to agitator clearance, if you don't get the tinking sound with an empty bowl but only when there is dough in the bowl the bowl tabs aka "ears" are worn and not locking the bowl down securely allowing the pull of the dough to lift the bowl slightly which allows the agitator to contact the bowl bottom. Try holding the bowl down securely in place while mixing a dough, if the tinking sound goes away you know what the problem is. A little bit of this isn't a big issue for now, but over time the bowl locking pins will wear and the problem will get worse eventually leading to the bowl jumping off of the arms while a dough is being mixed. I've seen this on any number of mixers over the years, the only real solution to the issue is to either replace the pins or get a new bowl, or both. Some of the smaller mixers (N-50) used to be equipped with a locking mechanism to lock the bowl onto the pins (all of the large mixers have them but many of the smaller mixers don't). The locking mechanism used on the small mixers differs from those used on the large mixers in that it is shaped like a flat hook which is fastened to the bowl arms and moves

laterally so as to swing over the top of the bowl tabs thus locking the bowl down. Your mixer may have once had them or it may be possible to retrofit these locks onto your mixer thus preventing further wear.

[**Re: Refurb Commercial KitchenAid 8Qt**](#)**1158**

I'd go with 0.15 to 0.2% IDY with your dough management process. Using my dough management process I normally use 0.3%.

[**Re: In cold fermentation, does it matter when I ball the dough?**](#)**1159**

With regard to weighing the yeast, if your scale will not weigh 1-gram then try this, weigh 5-grams and put it into 50-grams of water, stir well to suspend the yeast in the water and then weigh 11-grams of the suspension. Within that 11-grams of yeast suspension will be 1-gram of yeast. Discard the remainder of the suspension or make some bread with it.

[**Re: Over fermentation issues \(CY or Flour issue?\)**](#)**1160**

Are you saying that the dough balls represented in the picture are over fermented?

[**Re: Over fermentation issues \(CY or Flour issue?\)**](#)**1161**

Not too shabby! :chef:

Now you can begin experimenting with the dough formula to achieve the characteristics you're looking for which will make it "YOUR" pizza.

[**Re: Almost same formula, 5 times the amount of yeast. Am I missing something?**](#)**1162**

We need to know what your finished dough temperature was, and yes 1% IDY was too much yeast. I would have suggested using 0.25 to not more than 0.3% IDY for a 72-hour fermentation period. You also want to use the SAF (RED LABEL) yeast, NOT the GOLD LABEL, as stated, the gold label is a high sugar tolerant form of IDY BUT it also has a very low tolerance to salt. Typically we see a slowing of fermentation rate when salt levels above 1% are used with this type of yeast. My guess is that your finished dough temperature was too high which would explain the fermentation rate which you were experiencing, a good finished dough temperature to target is 70 to 75F/21.1 to 23.8C.

[**Re: Can I fix a dough with too much yeast?**](#)**1163**

Can you provide us with a photo of the over proofed dough balls? Too bad the video didn't show a fast forward of the dough balls after 6 to 8-hours.

[**Re: Almost same formula, 5 times the amount of yeast. Am I missing something?**](#)**1164**

Matt;

Go to Bulbtown@bulbtown.com/www.bulbtown.com to see what they have in their very vast inventory of bulbs. In addition to a huge selection their prices are very good too, we buy all of our landscape light bulbs from them.

[**Re: Mini lightbulb question**](#)**1165**

With 0.5% CY and 60% dough absorption and less than 24-hours total fermentation time the dough should not be over fermented however that doesn't mean that the flour/flours that you are using have sufficient fermentation tolerance to allow the dough to be fermented for more than about 12-hours. A quick way to test for this is to replace your existing flour blend with 100% bread type flour, if the dough performs better you will know what the issue is. This is based on the assumption

that you have the finished dough temperature under control in the 75 to 85F range, if the dough is any warmer than this it can accelerate the fermentation rate resulting in the potential for dough collapse.

[Re: Over fermentation issues \(CY or Flour issue?\)](#)**1166**

Only if the total dough weight is 20-ounces or more.

[Re: In cold fermentation, does it matter when I ball the dough?](#)**1167**

The non-stick finish on the Lloyd's Pans WILL NOT come off. We used them for MANY years and never had a problem with the finish, I used to demonstrate the durability of the finish (you can do this yourself) by rubbing the edge of a quarter briskly across the pan, the quarter would be abraded as demonstrated by a flat spot where it was rubbed on the pan but absolutely NO damage to the pan or its finish. I can also show you pans that have been in commercial (pizzeria) use daily for over 10-years and the finish is still intact. If you want some pans without any finish on them you might look into cake pans, these are usually available in steel or aluminum, remember though that you will need to season these pans prior to use and you will need to be highly protective of the seasoning by never soaking the pans in soapy water or allowing them to remain wet for any length of time, failure to do this will result in the seasoning coming off of the pans like a bad sunburn, you will then need to strip all of the seasoning off of the pan and start all over again. One last thing, with the Lloyd's pan, it will need to be washed (soapy water will not harm it) prior to the first use, it should then be lightly oil for the first bake, after that the use of oil in the pan is optional. We always use a light application of oil for the deep-dish pizzas but never oil the Lloyd's disks for thin crust pizzas. To clean the pans and disks just wipe them off using a clean towel and they're ready for the next use.

[Re: Sicilian, Detroit and Chicago deep dish pans in Germany](#)**1168**

From the title of the post I was expecting this to go in a totally different direction.

:D

[Re: Your favorite Instant Pot recipes](#)**1169**

The benefits of bulk fermentation are essentially non-existent with such a small size dough. You could just as easily scale and ball the dough right after mixing and I'm betting you would get the same results. Your IDY percent is OK for up to about 3-days cold fermentation. Try this, after mixing, scale and ball the dough, cold ferment for 3-days, remove from the fridge and allow to warm until the internal temperature of the dough ball reaches 60F/15.5C before you begin opening it into a skin.

[Re: In cold fermentation, does it matter when I ball the dough?](#)**1170**

Please refer back to my above post.

[Re: In cold fermentation, does it matter when I ball the dough?](#)**1171**

The research that we did at AIB indicated that a dough which expands more during baking (increased oven spring), for whatever reason (including increased dough absorption) will produce a crispier finished crust. In a deck oven or stone hearth oven the crust is being baked at a much higher temperature than the toppings due to the evaporative cooling effect of moisture in the sauce and toppings.

[Re: Correlation between hydration and cook temp and time](#)**1172**

From personal experience I personally like the Rocker Knife (PKR20) because it

seems to work better with deep-dish pizzas than the (PPK17) and it cuts all the way through the edge crust better on thin crust pizzas but in the end I think it all comes down to personal preference.

[Re: Cant Decide between rocker knives](#) **1173**

JPChicago;

The delayed oil mixing method was not used in bread production during the time your father was employed in the baking industry as the type of fat used in wholesale bread making at the time was either a plastic fat (shorthening) or liquid bread shortening both of which really don't require a delayed addition like vegetable oil does. Today vegetable oil is much more commonly used and it is metered into the horizontal mixer at the end of the first minute of mixing.

As a side note, I'm also from Chicago (far south side) Tinley Park. During the very early 60's I worked in the Jewel Tea Bakery, 1955 W. North Avenue, Melrose Park, IL. There was also Burney Bros. Bakery, Sara Lee Bakery, Gonella Bakery and a sweet goods/pastry bakery whose name I don't remember anymore as well as two bun plants which made buns for McDonalds. Just out of curiosity, can you share with me what years and which bakery your father worked at?

[Re: When to add the oil](#) **1174**

It is impossible to fully answer your question without knowing a lot more about the dough in question which is probably why you have had a problem finding a definitive answer, and even then the answer will be specific only to YOUR dough. The factors which would influence the answer to your question would include such things as;

Dough formulation.

How and how much the dough has been mixed.

The finished dough temperature.

Size/weight of the total dough as well as the weight of the individual dough balls.

Type of container(s) used to ferment the dough as well as the dough balls in.

The strength of the flour.

Actual room temperature.

[Re: In cold fermentation, does it matter when I ball the dough?](#) **1175**

Whereas Danish butter is relatively pliable even when taken right out of the fridge and it doesn't melt like our regular domestic butter does. The Lakpur brand is what we have available to us here in Manhattan, KS. Once you try it in pastries you will never use domestic butter again.

[Re: Blitz Pastry method?](#) **1176**

But, keep in mind that when using the delayed oil addition method of mixing the gluten development isn't impaired.

[Re: Using oil to intentionally weaken dough](#) **1177**

Try this, after allowing the biga to ferment overnight add the remainder of the water to the mixing bowl along with the salt (no need to mix), then add the remainder of the flour (all of it), and mix at low speed until the biga and flour are incorporated, then mix at a higher speed for at least 5-minutes. Let me know what the dough looks like.

[Re: Need help with biga dough](#) **1178**

I just checked my pans, you are correct. The pans are tapered.

[Re: Pizza Hut pan specifications](#) **1179**

The purpose of adding oil is not to hinder gluten formation but instead to provide flavor both directly (flavor of the oil) and indirectly (oil holds/retains flavors). It also lubricates the dough for improved expansion properties as well as coating the cell structure for improved gas retention both of which result in better oven spring. Oil also exerts a tenderizing effect upon the crumb resulting in a less chewy finished crust which is achieved through the lubricating effect as mentioned above.

Old school is to add the oil to the water and mix together (why?) it will not form an emulsion. The oil immediately separates from the water and floats to the top of the water, when the flour is added the oil is absorbed into the flour rendering a portion of the flour incapable of forming gluten which leads to perceived inconsistencies in dough absorption and very real differences in dough handling properties. By using the delayed oil addition mixing method the water is added first (salt and sugar can be added to the water if desired) and then the flour is added along with the yeast, it is then mixed until no dry flour is observed in the bottom of the mixing bowl, the oil is then added and incorporated while mixing at low speed, once the oil is incorporated at low speed the dough is mixed at a higher speed to develop the gluten to a point where the dough takes on a smooth, somewhat satiny appearance. This is all the gluten development needed or desired for pizza dough production that will be further subjected to a period of fermentation. Putting oil into an autolyze is, in my opinion counter productive since the function of an autolyze is to achieve better hydration of the flour, this is especially so when high dough absorptions are employed.

[Re: Using oil to intentionally weaken dough](#) **1180**

If you REALLY want to see what the crumb structure looks like do as we did when we did our research on pizza, turn it over and cut it from the bottom up using a razor knife or a VERY SHARP serrated knife. This way you do not drag the sauce and cheese down over the crumb as you do when you cut the pizza from the top.

[Re: Question about cutting the pizza](#) **81**

It sounds like you are not allowing sufficient time between bakes to allow the stone to fully recover its latent heat (in short, the stone is cooling off). If your oven has bottom heating elements you will need to move the stone closer to the heating element to speed up the recovery time or get a thicker stone, maybe a baking steel. It looks like you are using a "00" flour so you may find that you will need to increase the sugar level to achieve top crust color after moving the pizza stone closer to the bottom heating element. Assuming that you are allowing at least an hour for the stone to fully heat up?

[Re: Bottom not cooked?](#) **82**

The only work that I've been involved in with amylose, not high amylose (starch) flour was in research on low calorie bread back in the days of low calorie breads in the early 1970's. Since amylose is a resistant (non-digestible) starch we were looking at it as a possible substitute for micro-crystalline alpha cellulose in making bread similar to the then popular New Horizons low calorie bread. We don't fully understand the bread staling phenomenon even today. It has been shown to be at least partially due to retro-gradation (crystallizing) of the starch while other studies have implicated the protein fraction of the flour more than the starch fraction. Some of the more effective enzyme anti-staling agents used in white pan bread production are based on the starch model. These use a heat resistant amylase enzyme to hydrolyze a portion of the starch in the baked bread, thus releasing its bound water making for a softer, more moist crumb structure which

the consumer perceives as being less stale. Since a resistant starch would resist being hydrolyzed it would remain intact, acting more like a fiber than a starch, hence, there is less starch present to participate in the staling process. I would guess if it's a softer pizza that you're after this might be something to look at in greater depth. I've never looked at staling as an obstacle to be overcome with pizza since many of the characteristics of staling are the same characteristics that we are trying to achieve in pizza. Take par-baked crusts for example, most would agree that they make pretty decent pizza (both thick and thin crust), a crust can't get much more stale than a par-baked one and yet we still think it's pretty good in many cases.

[Re: Low amylose flour? 83](#)

Scott;

Not that I'm aware of, by design they all round a pretty tight ball. The rounding bar is the only truly adjustable rounder but when getting a loose ball you also get a poorly rounded ball.

[Re: Rounder and dividers 84](#)

That's correct, there is indeed calcium in the mozzarella cheese too but it doesn't interact with the sauce in the same manner as a fine powdered cheese does, just like swallowing a piece of chalk doesn't work as well as drinking the milk. Which is probably why they don't say to eat a piece of cheese to counter the effects of ingesting an acid or alkali as much as we might like to it just doesn't work as well :-D.

I use Parmesan and/or Romano as I'm always trying to up the flavor profile of the mozzarella cheese. If I'm not worrying about the acidity of the sauce my preference is to use shredded Parm and/or Romano in addition to the mozzarella.

[Re: Which are the factors that affect digestibility? 85](#)

My all time favorite is just Stanislaus 7/11 Ground Tomatoes (with peel). Use it straight from the can with nothing added, then add a little fresh basil (sliced into strips) and maybe a little crushed garlic over the top of the sauce, add the cheese and dress to the order. DO NOT add any garlic or onion product to the sauce! This will act as a catalyst resulting in gelling of the tomato pectin within 24-hours. If you JUST GOTTA have garlic or onion in the sauce put it in a small amount of oil and nuke it to over 190F to deactivate the enzymes responsible for the gelling of the tomato pectin, then add it. I don't like doing this as it potentially reduces the flavor impact of the onion/garlic.

[Re: Newbie with a sauce question 86](#)

I got the idea to pursue this about 25-years ago when I was reading an article on what to do if someone ingests different poisonous/harmful materials. One of the things mentioned in the article for acids or caustics was to drink milk as the calcium content works to buffer the acid or alkali, this got me to thinking about the acidity of the tomatoes, and sure enough it appears that the calcium content of the cheese works in a similar manner to that of whole milk as it also seems to buffer the acidity of the tomato in the sauce and the flavor is right at home on a pizza too. Just goes to show ya, answers to problems can often be found in the darnedest places.

[Re: Which are the factors that affect digestibility? 87](#)

Does Combs, St. Paul or Pettigrew ring a bell with you? Just wondering (they're in N.W. Arkansas).

[Re: New member from Arkansas](#) **88**

My guess is that the dough was over fermented to the point where it was becoming "bucky", when it's like that the dough will exhibit very elastic properties with any work put into it, like trying to open the dough into a skin. Best thing to do in a case like that is to re-ball and play the waiting game until the dough relaxes again which will allow it to be opened into a skin relatively easy.

[Re: Dough is out of control!!](#) **89**

If the pizza has a crispy crust it has to be somewhat dry resulting in some thirst....hence its popularity as a bar food. Eat pizza = drink more beer! ;D If you use a tomato based sauce it's always going to be a bit acidic as tomato is an acidic fruit. You can tone this down a little by adding a powdered cheese (Parmesan & Romano) to the sauce. The calcium content of the cheese helps to balance the acidity of the tomato.

[Re: Which are the factors that affect digestibility?](#) **90**

The Dutchess divider/rounder machines aka "shaker machines" are great machines and have been around for a very long time. ^^^ I see you have the steel platters (as they are called), these are (in my opinion) better than the plastic ones. When set-up to do a 36-piece divide& round they are the industry standard for making small scale hamburger and hot dog bun production runs. :chef:

[Re: Rounder and dividers](#) **91**

With those conditions the dough will not be properly baked out, so in that case I would expect to find that it has an alcohol aroma, the same would be said for raw dough which the dough that you've described is just half a bubble off of.

[Re: Effect of hydration; is there a simple answer?](#) **92**

No, not always. Flour characteristics, dough formulation, fermentation and bake will be the major contributors to chewier eating characteristics.

[Re: Higher hydration doughs](#) **93**

While you're at it get yourself a dial/stem type thermometer too as you will want to have one so you can measure the water and dough temperatures. Additionally, do you have an oven that gets hot enough to bake a pizza made with "00" flour? The oven needs to be able to reach temperatures north of 750F, if not, you would be better served using a domestic bread type flour.

[Re: Dough is out of control!!](#) **94**

Even when alcohol is added to the dough, such as in the case of making a beer crust, there is no additional residual alcohol in the finished crust....it's that volatile.

[Re: Effect of hydration; is there a simple answer?](#) **95**

You're going to have to experiment to find out. The key is in having sufficient R.H. to prevent a skin/crust formation on the dough. A good way to do this at home is to place a wet towel in the area where the donuts will be proofed (an insulated ice chest works well) and prevent exposure to drafts.

[Re: Yeast donuts recipe?](#) **96**

Welcome!

Where abouts in Arkansas?

[Re: New member from Arkansas](#) **97**

Sandruz;

Just confirming that you are pre-hydrating/activating the ADY prior to addition and not just adding it dry as you would IDY. You can save yourself some work by doing the following:

- 1) Add the ADY suspension to the dough water and mix into all of the flour.
- 2) Add the salt directly into the flour in step #1 above.
- 3) Mix the dough at this point until it just until all of the flour has been whetted, then add the oil and mix for 1 additional minute at low speed, then mix at medium speed just until a smooth dough appearance is achieved.
- 4) You're not going to see much, if any difference between "bulk" and ball fermenting with such a small dough size so you could ball and CF after 50-minutes room temperature fermentation if you wish.

Note: This all all based on the assumption that you are machine mixing.

[Re: Advice on the moment of balling and delayed oil](#) **98**

The preferred way to add IDY is to add it to the dough after a few minutes of mixing providing that the dough will be machine mixed for a minimum of 5-minutes after the IDY has been added. The second preferred method, and possibly the most used, is to add it directly into the flour. By design, IDY hydrates very quickly (that's where the "I" comes from), so it is easily damaged if not properly hydrated (95 to 100F water). Yeast will exhibit about a 20-minute lag phase after addition before it begins to actively ferment in a dough environment at a temperature between 70 and 85F.

[Re: Autolyze experiments](#) **99**

An autolyze is necessary when using whole-wheat flour or any type of multi-grain blend (lots of discussion on this), and it is also useful when working with high absorption doughs (over 70%), as well as when mixing the dough entirely by hand. When machine mixing I've never found any great advantage to using an autolyze. In my world an autolyze is what the old time bakers used to refer to as a "soaker" consisting of just flour and water. As soon as you put yeast into the picture you no longer have an autolyze, but instead you now have what's called a biga, a sponge or a brew. It has a very different effect on the flour than an autolyze.

[Re: Autolyze experiments](#) **100**

Please share your entire dough mixing process.

[Re: Need help with biga dough](#) **1181**

It's a straight sided pan. The deeper pan allows for better protection of the toppings from getting scorched during baking. You might also want to get a deep pan gripper while you're at it too. A 1-inch wide flexible blade cake decorating spatula is the preferred tool to use for running around the side of the pizza and to help glide the pizza out of the pan. DO NOT USE A KNIFE!

[Re: Pizza Hut pan specifications](#) **1182**

You have a biga and you have a dough, I will assume that you want to use all of the flour in the biga and none in the dough side. I will also assume that you want to ferment the biga for 24-hours at room temperature/ambient (whatever that might be), based on these assumptions I would suggest using 0.25% CY in biga #1; 0.15% in biga #2 and 0.1% in biga #3. For IDY use only 40% as much IDY as you did CY.

[Re: Recipe for dough with 100% biga](#) **1183**

Nothing if the picture is of the biga, if it is of your dough its under mixed.

[Re: Need help with biga dough 1184](#)

As a reference most pizzerias are paying around \$3.00 plus change per pound for Grande shredded.

[Re: Grande Cheese \\$25 for 5lbs? Is it worth it? 1185](#)

We used to have a bunch of old P.H. pans at AIB. They were nesting pans with a horizontal line indented in the pan about 5/8-inch above the bottom of the pan, this was the height to which they would proof the dough to.

[Re: Pizza Hut pan specifications 1186](#)

No, it's not just in your head. You are spot-on. Anytime non-gluten forming flours are added we always use a sufficiently strong flour to make up for the dilution of the gluten by the non gluten forming flour(s).

[Re: Considerations when adding chia, flax, other seeds to dough? 1187](#)

Please excuse me for my confusion, but a "biga" made with 45% absorption, wouldn't it be a sponge rather than a biga? I normally think of a biga as being made with 60% absorption or more.

You mention adding water until the dough is 65% hydrated but what is the total dough absorption? For example, if the total dough absorption is 68% and you add water until it is 65% hydrated wouldn't you be adding just 65% of 68 or 44.2% absorption? Or maybe the use of the word "hydrated" is incorrect in this instance and maybe you mean 65% absorption? To answer your question regarding the yeast amounts we would need to know at what temperature you plan on fermenting the biga at.

[Re: Recipe for dough with 100% biga 1188](#)

It certainly can as the diastatic malt will convert starch into fermentable sugars but 2% is a high dose of diastatic malt, if you are experiencing stickiness of the dough it is most likely due to the high malt level, in that case just begin backing it down to eliminate the stickiness.

[Re: Is my dough still good 1189](#)

Measure the internal dough ball temperature at the time of opening, by doing this you will be able to temper the dough ball to this same temperature any time of the year, regardless of room temperature and the dough will always perform/handle in a similar manner. Most pizzerias allow the dough ball to reach 50F before opening but many home pizza makers will allow it to reach a higher temperature with 60F being a pretty common temperature, just remember that the higher the dough temperature the more difficult it can be to open if you are not proficient at opening a dough ball into a skin.

[Re: Mixing Times 1190](#)

3 to 4-days is what one might refer to as the suggested optimum, it can still be good to use for some time after that. It all depends upon how well the dough was refrigerated as well as the freshness of the CY and the strength of the flour.

[Re: Is my dough still good 1191](#)

For bread you are going to have a tough time with a 50/50 mix, I suggest starting with a 65/35 blend (35% being the seeds). You will need to pre-hydrate the seeds prior to addition to the dough. If you will go back into the archives you will find

where I've provided instructions on how to find the optimum absorption for the multi-grain blend of a multi-grain dough. It's important to get this right as it will have a huge impact upon the finished bread quality as well as the quantity of seed that can ultimately be incorporated into your dough. Remember to develop your seed blend first, then do the absorption determination, if you change the seed blend composition the absorption will change and you will need to find the absorption of the new blend.

You will also want to keep your total dough fermentation time on the short side (6-hours?) and is adding a sour don't get too heavy handed as both fermentation and the sourdough starter will weaken the dough making it more difficult to carry the seeds without collapse.

[Re: Considerations when adding chia, flax, other seeds to dough?](#) **1192**

Sure, Any regular dough formula will work for this WITH the following changes;

1) Increase fat content to 10% in the form of butter or margarine (Danish butter works far better than any other type of butter).

2) Freeze the butter and cut into peanut size pieces (keep frozen).

3) Mix the dough as you normally would (just until smooth), then add the butter and mix in just until the butter pieces are incorporated into the dough). In don't mean as a part of the dough, you just want to have the butter pieces incorporated as pieces in the the dough).

4) After mixing, turn the dough out of the bowl and sheet the dough using a rolling or pastry pin to about 1/2 to 3/4-inch thickness and give it a 4-fold (Google it if you don't know how), then cover with a sheet of plastic for 20-minutes and give it a 3-fold and wrap in plastic and refrigerate for 24-hours.

Remove dough from fridge and allow to warm to 55F, then sheet out to desired thickness (3/16 to not more than 1/4-inch thick, unless you're making a pan style pizza, then sheet it to 1/2-inch thickness) cut to desired diameter, dock with a blunt dough docker, dress and bake.

This will give you a crust similar to the old Tony's Italian Pastry Style Crust (frozen pizza).

[Re: Blitz Pastry method?](#) **1193**

That's my kinda pizza! Looks GREAT!

Tom Lrhmann/The Dough Doctor

[Re: Is my dough still good](#) **1194**

I was in charge of the Experimental Baking Group at AIB when the bromate thing hit the fan and we all had a good idea of what was to follow so we embarked on a rather lengthy study both in-house and through collaboration with the baking and allied industries to find an acceptable substitute for potassium bromate. The study continued for several years and during that time we all learned a lot about how different dough strengtheners work both by themselves and when used in combination with other dough strengtheners. Today we (the baking industry) have some excellent oxidative enzyme type dough strengtheners to work with as a replacement for potassium bromate but for the most part they are only used in very specific applications such as frozen dough and some specialty breads and are not generally in wide use for a couple of reasons such as:

1) We found that bromate really wasn't needed except in continuous mix bread aka batter whipped bread (common in the 50's and 60's), instead it was being used as a crutch to help maintain product quality with less than stellar performing flours available at the time.

2) Wheat breeders were developing new and stronger wheat varieties for the then

popular continuous mix bread processes BUT as continuous mix bread fell from popularity (rightfully so) by the early to mid 70's the baking industry had flour being supplied to it by the millers that was too strong for the bread making process which replaced continuous mix bread, the sponge and dough bread making process. In some bakery plants they used a flour brew process where 30 to 40% of the flour was fermented in the liquid brew (think biga), in this case the new flour created even more issues as the brew flour could not be increased above 40% due to gluten separation so the finished breads were always showing signs of excessive strength (too much volume/height and wild break and shred) were critical issues as the faults interfered with high speed bagging of the bread.

3) Issue #2 above was of the highest critical nature to the baking industry at the time (we also worked on that too as we began researching ingredients known as "reducing agents") which included things like L-cysteine, glutathione aka dead yeast, various vegetable powders (onion and garlic), potassium sorbate and a few others). With #3 resolved, the baking industry seemed to settle down and began making decent bread once again and with the stronger flours available they soon learned that bromate really wasn't all that necessary so when the bromate replacers became available they were pretty well met with a yawn except for a few specialized applications like the frozen dough previously mentioned.

4) Due to the growing consumer concerns over the use of bromate most bakeries readily deleted bromate from their dough formulas with no ill affects to finished product quality.

Today flour can still be had that is bromated but there are strict Federal guidelines limiting how much bromate (in total) can be used. For the most part we can buy flour in 50# bags that is either bromated or non-bromated, your choice. As a side note, Interstate Brands Corporation Bakeries began producing a white pan bread which they called "Grandma's Bread" this bread was unique for the time in that it was made with a non-bleached flour, this means the flour had a natural creamy/yellowish color and the finished bread had a corresponding yellowish crumb color, they opened the gap on their sheeting rolls at the moulder for a slightly more open crumb structure and a whole new direction was created for white pan bread, that was one of "old fashion", like grandma used to make. From that point on most flour being shipped to bakeries was now un-bleached. This still exists to this day.

It's really fun and interesting to see all of this unfold especially when you're in the thick of it and in some way you realize that history is being made before your very eyes and you're a part of it.

How sad to see AIB go the way of the DODO BIRD as no one will ever be able to have such great exposure in the future.

That's our trivia lesson for the day.

[Re: Local opinion piece, bleached vs unbleached](#) **1195**

So? where did the numbers come from?

The formula of 140 minus flour temperature = water temperature is correct for doughs having a targeted finished dough temperature in the 82 to 88F range. It comes from the Red Star "Directions for Use Guide doe Instant Yeast".

The 130 minus flour temperature = water temperature is correct for use with doughs having a targeted finished dough temperature in the 70 to 78F range. As there are so many variables involved with mixing a dough one has to keep in mind that these formulas are not precise but they will get you close to the temperature range you want your finished dough temperature at. This will allow you to easily adjust the water temperature (in 5F increments) for following doughs

to zero in on the exact water temperature needed to give you the desired/targeted finished dough temperature you want for YOUR specific dough formula mixed in YOUR mixer in YOUR kitchen/shop.

[Re: Describing the feeling of finished Dough 1196](#)

Don't worry about the black spots, if anything the dough actually looks to be a bit under fermented.

[Re: Is my dough still good 1197](#)

Just guessing, 0.375% IDY and 62% dough absorption.

[Re: Sourdough Bread Machine Flour Mix 1198](#)

How in the world do you come up with 130F water temperature? 145 minus flour temperature (45F) = 100F water temperature. If you are using flour right out of the fridge you might be better off bringing it out the day before you plan on using it and putting it in a bowl to warm to room temperature. The warmer flour will hydrate much better and more quickly during the mixing process which is better suited to the high speed mixing of a food processor.

[Re: Describing the feeling of finished Dough 1199](#)

It would read better if he/she knew what the hXII he/she was talking about!

1) Need to study up on why bleached flour became popular in the U.S.
2) KBRO₃ is indeed a known carcinogen but it is converted to bromide (which is safe) during the baking process and KBRO₃ was never detected, then in the 1970's the Japanese perfected a test procedure that could detect KBRO₃ in ppb (parts per billion) not ppm (parts per million) as previous tests could detect. They found trace amounts (ppb) of residual KBRO₃ and it was immediately banned in many countries. Today the legal limit for KBRO₃ is 15-ppm at which level residual even at ppb cannot be detected.....argument: "but that doesn't mean it isn't there". By that logic I guess we should stop eating eggs and ground meat since both are assumed to be E-coli positive (now you know why you should not eat raw/uncooked hamburger or eggs, yes that includes cake and cookie batter too (no more licking the bowl). But wait, doesn't cooking kill the bacteria? Yes it does, but does it kill 100% of it? You won't know for sure unless you test what you are about to eat, so lets just avoid eating ground meat and eggs as well as anything made with them. This seems absurd to me, in view of what is in our drinking water, in the pure city air which we breathe, in the city swimming pool (speak of chlorine), how about the mercury in the ocean fish that we eat? It just goes on and on and on, I for one, decided a long time ago to cut my losses and stop worrying about the foods that I eat, I believe in redeeming social value, by this I mean I select foods that are known to be more nutritious such as whole wheat breads/flours, etc. and I really don't care much about the "additives" in them, I eat potatoes but always order with the skin on if possible, I never peel an apple (not even when making apple pie), I drink juices with the pulp (fiber is good for us). Worrying about too many things will give you high blood pressure or an ulcer and in my world those are also dangerous and should be avoided too.

Eat and drink in moderation and be merry!

As for being banned in Europe, true, it is, but then so is aluminum as it pertains to any kind of food. Why? Because a researcher found aluminum in the brains of persons who had died with Dementia so aluminum (yes pots and pans too) were immediately banned. We've all seen pock marked aluminum pots and pans, now you know where all that aluminum went! False! It doesn't quite work that way, and the aluminum found in the brain matter was discovered to be normal

[Re: Local opinion piece, bleached vs unbleached](#)**1200**

John;

Do you mix to temperature or time?

[Re: Describing the feeling of finished Dough](#)**1201**

If the dough is over fermented you will find that the dough is too extensible, it may also be sticky and it can collapse under the weight of the topping ingredients resulting in a tough, chewy finished crust. If the dough is REALLY over fermented it will become "bucky" (difficult to stretch without it tearing), it may also exhibit excessive memory characteristics at opening resulting in the dough continually snapping back, note that under fermentation will impart a lot of the same characteristics as excessively over fermented, the main difference being that the under fermented dough generally doesn't tear as readily.

[Re: Describing the feeling of finished Dough](#)**1202**

It appears to be an inactive sour which is designed to provide a flavor only (hence the need to add yeast). We recently had some discussion here on a similar product from Red Star.

[Re: Sourdough Bread Machine Flour Mix](#)**1203**

I think your problem stems from the use of a sheeter to open the dough. The sheeter at least partially degasses the dough and at the very best creates a small, bread like cell structure in the dough (in fact, this is exactly how we get that nice, small/fine crumb structure in white sandwich bread). There are a few things that you can do to achieve the characteristics that you are looking for, first is to optimize the dough absorption. To do this begin increasing the dough absorption by 5% (from the appearance of your dough it appears to be a bit low in absorption for what you are trying to achieve) then make 2% adjustments after that if necessary. The softer dough will more readily expand during the proofing period and during the oven spring phase of baking. If your final proofing time is still too long (more than 75-minutes) increase the amount of IDY to 0.4%. I don't know what you are looking for in the finished crust but for a pan style pizza your dough looks to be kinda thin in the pan so you might also want to experiment with trying a heavier dough weight in combination with the above recommendations. I'd suggest trying a couple pizzas each with a dough weight of 18, 20 and 22-ounces. With the heavier dough weight you will get a more pronounced raised edge during the baking process if that's what you are looking for.

By the way, when I make deep-dish pizza my dough scaling weight for a 12-inch pan is 16-ounces which is a dough loading of 0.14159 (ounces of dough per square inch of pan surface area), based on this I would use 21.8-ounces of dough in a 14-inch pan.

[Re: Dough Doctor's Basic Dough Recipe](#)**1204**

What is the dough weight that you're using for that pizza and what is the diameter? After the CF period are you allowing the dough balls to come up to at least 50F before opening them?

It appears that you are opening the dough using a sheeter, is this correct?

The pan shown appears to be a 1-inch deep pan, what is the target thickness for the finished crust?

I have an idea of what the issue is but I just need a little more information.

[Re: Dough Doctor's Basic Dough Recipe](#)**1205**

Your problem could be due to insufficient yeast, excessive salt, insufficient sugar for the dough management procedure being used and probably a few other things too but I could do a much better job of answering your question if I could see your entire dough formula as well as dough management procedure.

By the way, when mixing large doughs like that we typically have to use 65 to 70F water temperature. A quick and easy way to find the desired water temperature is as follows: 145 minus flour temperature = water temperature for a finished dough temperature in the 80 to 85F range.

[**Re: Dough Doctor's Basic Dough Recipe**](#) **1206**

Josh;

Many home type mixers are actually pretty efficient at mixing dough so don't count them out as inefficient, also we can make up the difference in time by mixing at a higher speed (more r.p.m.). While mixing is important from a commercial point of view in that it allows for faster, easier handling of the dough (a sticky dough really bogs things down in a pizzeria when we're trying to scale and ball the dough) it is not nearly as critical when making pizzas at home as we are dealing with only a few pizzas at a time. Remember, the main reason for mixing to get that dry, smooth skin is to facilitate dough handling only. If you don't mind putting up with a sticky or tacky dough you could actually stop mixing as soon as the dough forms a ball that doesn't look like "brain matter" about 5-minutes into the mixing process after adding the oil.

We teach a true no-knead mixing process to home bakers and it involves mixing with a wood spoon, no kneading or anything else. The resulting dough looks like oatmeal, it is transferred to an oiled bowl, the dough itself is lightly oiled, it is then covered with a piece of plastic and allowed to room ferment for 2 to 3-hours, it's turned out of the bowl, kneaded a few times and balled then placed back into the oiled bowl for another 3-hours. It is then turned out of the bowl and divided into multiple pieces for our pizzas or made into a single pizza depending upon the dough size. The resulting crust eats quite tender and has an open, porous crumb structure. Not too shabby for pizza made at home from a dough that didn't need any kneading. The process also makes great bread too, I normally make round loaves from this dough.

Your proposed method for measuring the temperature in the refrigerator is the same that we used except that we used oil instead of water since it doesn't support microbial growth.

[**Re: Mixing Times**](#) **1207**

Peter;

I'd almost forgotten about that video. What a trip down memory lane! That's an excellent video on the entire dough mixing process as well as dividing and balling/rounding the dough. Can you put the video into the "tool box" for easy future reference? I'm really glad that we got all of our pizza research done when we did, AIB is no more, and I don't know of any research facility that is doing or has interest in doing both basic and applied research on pizza.

[**Re: Describing the feeling of finished Dough**](#) **1208**

As soon as the dough has a smooth appearance you're done with the mixing process. Biochemical gluten development will take care of the rest for you during the fermentation process.

[**Re: Describing the feeling of finished Dough**](#) **1209**

Your pizzas are not round? Nothing wrong with this but it might be indicative of an

underlying dough or formulation issue? Is your dough soft and extensible at opening, or does it tend to fight you (too elastic)?

[Re: stretching and lunching methods](#)**1210**

No, because you are just pushing the top of the dough down so you're still reading the temperature at the top of the dough, plus the area that the IR thermometer is reading (collecting data from) is larger in diameter than a finger poke thus leading to an incorrect reading. The only way we were able to get consistently accurate internal ball temperature using an IR thermometer was to actually cut the dough ball in half and measure the temperature of the center portion. This was the only way we could get meaningful data on frozen dough balls too when we were doing studies on freezing of different type of dough and had to accurately measure the internal ball (core) temperature. The solidly frozen outer shell of the dough ball prohibited us from using a dial/stem type thermometer. We once used a drill to drill an entry hole to insert the stem into, this worked but it was a real pain. Ultimately we used a meat cleaver and a chopping block to split the dough balls in half allowing us to measure the temperature more quickly using the IR thermometer.

[Re: Mixing Times](#)**1211**

While not technically the same (Absorption is a characteristic of flour to take up and retain water or other liquid, expressed as a percent of the flour weight) while (Hydration is the ability of flour to absorb water or other liquid, there are two aspects to hydration, 1) Total amount of liquid absorbed and 2) The rate at which it is absorbed) the two terms are used interchangeably by home bakers.

[Re: Correlation between hydration and cook temp and time](#)**1212**

I also just "crunched" your numbers. Your 10-inch skin has 2.80-grams of dough for each square inch of surface area while the 12-inch skin has 2.74-grams. So, if the 10-inch is OK your dough weight for the 12-inch should be 316-grams + change (I'd call it 320-grams), not a big deal, but possibly a contributing factor.

[Re: Sauce running through dough](#)**1213**

An IR works fine at the mixer but you will need to use a dial/stem type thermometer to measure the internal dough ball temperature prior to opening.

[Re: Mixing Times](#)**1214**

CT;

An autolyse probably won't help much if any in this case.

Do Not Mix To Temperature! Instead, mix the dough just until it becomes smooth, then measure the dough temperature. Adjust the finished dough temperature of following doughs by manipulating the water temperature up or down as needed to give you a finished dough temperature in the 70 to 75F range. When adjusting the water temperature move it in 5F increments.

DO NOT allow the dough to warm to room temperature, instead, allow it to warm AT room temperature until it reaches 50 to 60F. If you allow the dough to warm to a higher temperature (like room temperature) the dough will easily become almost too soft to easily work with, sound familiar?

[Re: Mixing Times](#)**1215**

I think your problem is due to the way you are opening the skin. You are opening it with thin spots rather than a relatively uniform thickness across the entire diameter of the skin. You might try partially opening the skin using a rolling pin or pastry pin, open the skin to within about 2-inches of full diameter and then finish

opening the skin to full diameter by table stretching. Not knowing your dough weight there is also a possibility that your dough weight is too light for the 12-inch pizza. Typically we see dough weights of 10 to 12-ounces used for 12-inch thin crust pizza skins. Remember, thinner does NOT make for a crispier finished crust. You might try using 12-ounces dough weight just to see if it helps resolve the issue, if it does you can fine tune the dough weight for the type of pizza you're making.

[**Re: Sauce running through dough**](#)**1216**

Wow! With an 18-inch pizza being 26% larger than a 16-inch pizza an 18-inch pizza selling for only a dollar more than the 16-inch is quite buy! Better keep that one under your hat. ;D

[**Re: Is it right formula??**](#)**1217**

And when you bake your pizzas remember to prevent any char on the crust as that has been shown to have some potential health issues too. Might as well stop breathing the air too or move to a mountain top home where the air is cleaner. Moderation, everything in moderation.

[**Re: Air Bubbles**](#)**1218**

Sure, that's how you optimize the dough absorption for a specific dough formula and management procedure.

[**Re: Dough Doctor's Basic Dough Recipe**](#)**1219**

Is the bubble formed inside the crust or under it? What does the bottom of the pizza look like?

[**Re: Air Bubbles**](#)**1220**

Steve;

Much of what you are asking can be found in the function of ingredients located in another section of this web site. As you have probably already noticed we don't like to deal with "recipes" more than we have to since a recipe is based on volumetric portions and as such are rather imprecise, whereas "formulas" are based on weight measures and are very precise and repeatable, additionally formulas are usually expressed in "bakers percent" where flour is always expressed as 100% and each ingredient is expressed as a percent of the flour weight. This allows for easy checking of the formula to determine if it is in correct balance and to see if any ingredient might be sufficiently high to impact the dough, dough handling or any of the finished product quality characteristics. Bakers percent also allows for very simple manipulation of the size of the dough while keeping all of the ingredients in correct proportion to the flour weight.

As to why we "tweak" formulas, it can be for a number of reasons such as, to better fit into our specific dough management procedure, to achieve a specific end product (crust) characteristic, to allow the dough to be better opened by a particular method, or to be better baked in a specific type of oven or specific oven conditions.

When I was teaching pizza classes I always told my students that knowing the function of ingredients allows you to effectively steer the dough or finished pizza to the characteristics that you are looking for. Take salt, for example, if the amount shown in bakers percent is less than 1.5% and the complaint is that the pizza crust has a bland or starchy taste the first action to take would be to increase the salt to at least 1.75% and probably not more than 2.5% (this is the normal range for salt addition in a pizza dough). On the other hand, if the yeast level is low and the salt level is high (3 to 3.5%) and the complaint is that the dough is difficult to open (too

elastic) the problem is most likely due to the high salt level slowing the rate of fermentation so in the end the dough is not getting sufficient fermentation to properly condition the dough/gluten for easy opening into skins. It's just like steering a car, you know that turning the steering wheel changes the direction of travel we do the same thing with our doughs only in this case our knowledge of the function of ingredients is the steering wheel while the dough and finished crust characteristics are the direction of travel.

If I remember correctly, I believe it was Pizza Today Magazine in which I wrote an entire article devoted to the function of ingredients, maybe Peter can find it in the Way Back Machine?

[Re: How do you know a dough recipe will be good? 1221](#)

This is precisely why I always tell people to use the "difference" in diameter as a percentage when pricing their pizzas. For example, a 12-inch pizza has 113-square inches of surface area and a 14-inch pizza has roughly 154-square inches, the difference being 41-square inches. If you divide 41 by 113 and multiply by 100 you get 36.28% which simply means that the 14-inch pizza is 36.28% larger than the 12-inch pizza. If you follow this simple math you won't fall victim to the size v/s cost issue shown in the video, remember that the underlying reason for being in business is to make money. Many of my followers have heard me ask a very basic question: "Why do you want to make different size pizzas?" The correct answer to this question is "so my customers can have more of the same pizza by ordering it in a larger format". If you can buy one 12-inch pizza pan for \$10.00 but want two, the cost will be \$20.00, it should be the same when buying pizza, unless you opt to make the classic blunder of discounting the price of your pizzas, that's a whole different story though.

[Re: Is it right formula?? 1222](#)

Visually, the dough balls look pretty good to me. The question is, do they open easily? Do they provide you with the finished crust you are looking for?

[Re: Dough Doctor's Basic Dough Recipe 1223](#)

Travis;

We've had a fair amount of discussion here on fermentation in ball form v/s bulk. A big piece of the puzzle is how big of a dough are we talking about. Look at it like this, if the bulk dough weighs 600-grams and the dough ball weighs 600-grams there will be little to no difference in the amount of fermentation the dough receives, assuming all things equal. If we have a 10-pound dough ball and bulk ferment it heat of fermentation/metabolism will increase the temperature by approximately 1F per hour of fermentation time but if you were to divide that dough into 1-pound pieces and ferment as dough balls the heat of fermentation/metabolism would be more easily dissipated in the smaller dough mass, plus it would show a greater response to the environment, warming faster in a warm room or cooling faster in a cold room. So, as you can see you need to know all of the details of the scenario in order to fully answer your question.

[Re: CF Bulk vrs Balled 1224](#)

You "might" be able to push the 40 to 50% mark but keep in mind that vital wheat gluten is very tough and rubbery so it has to be used judiciously. For each 1% VWG you add you will increase the protein content of the flour by 0.6%. It is generally accepted that 10% VWG is about the maximum you will want to add, and at that level you want to make sure the dough receives plenty of fermentation to help mellow the gluten making opening the dough a lot easier. One other thing, for each

1% VWG added you will need to increase the dough absorption by about 1.25%. ALWAYS be sure to disperse the VWG into the dry flour before allowing it to come into contact with any water.

[**Re: Dough Doctor's Basic Dough Recipe 1225**](#)

While Kamut flour is similar to wheat flour and it has a high protein content but it is lacking in the ability to produce a strong gluten matrix like wheat flour. For this reason it is almost always included in a blend with wheat flour usually at 25% or less of the wheat flour.

It typically exhibits a higher absorption value than many wheat flours due to its high protein content (it is the protein which carries a great deal of the water, however as this type of flour is usually more like a whole grain flour the presence of the bran (fiber) also exerts a great influence on the absorption properties.

Defatted soy flour, which has roughly 51% protein content, will typically carry its weight in water (100% absorption) is great for supplementing something with protein but it has no gluten forming proteins in its composition so it is also used in much the same manner where the amount used does not exceed much over 25 or 30% of the total wheat flour weight.

[**Re: Dough Doctor's Basic Dough Recipe 1226**](#)

Probably either the #4 or #6 speed, but in the end it will be the fastest that your mixer will easily handle the dough at.

[**Re: When to add the oil 1227**](#)

Most breads and rolls are going to be moulded/shaped by a rolling or folding process and any excess flour on the outside of the dough ball will be incorporated into the shaped dough piece resulting in large, undesirable holes and tunnels, pizza crusts, on the other hand, are formed by flattening the dough through a stretching process so no flour gets incorporated into the shaped dough so there is no issue with excess dusting flour on the dough and during the shaping process most of the dusting flour that is applied to the dough ball is removed by handling of the dough during the shaping process.

[**Re: Flour, sourdough loaves v. pizza 1228**](#)

A strong bread type flour will be best for that application.

[**Re: Dough Doctor's Basic Dough Recipe 1229**](#)

Some flours exhibit a slow hydration rate (this is also common to coarse ground flours too) which would explain why the dough seems to dry up as it ferments. You can easily get around this by using an autolyse as part of your dough making process, this is also beneficial if you are hand mixing your doughs too.

[**Re: Tough cornicione/pizza 1230**](#)

Depending upon the dough formulation it may or may not survive. Don't worry, it'll be safe to eat but it may not turn out as well as you hope. Just putting the dough back into the fridge will not quickly stop the fermentation process, it may continue for days in some home refrigerators. What to do? What to do? On the morning that you plan to make pizza later in the day re-ball the dough. Don't try to ball it tight, just get it into a ball shape, lightly oil it and place it back into the fermentation container. Pull the dough out of the fridge about 3-hours before plan to open it into a skin.

Some issues you may face:

- 1) The yeast ran out of nutrient and began cannibalizing itself resulting in a wet,

sticky dough with little oven spring.

2) The dough has become excessively acidic making the pizza difficult to bake properly.

3) The yeast has consumed all of the sugar normally used for crust color development making the pizza difficult to bake properly.

4) The dough becomes over fermented with all of the good things associated with an over fermented dough such as a dough that feels like putty, difficult to open without tearing, sticky, lacking oven spring, etc.

[Re: Is it safe to put dough back on the fridge?1231](#)

Most of the time the "stir" speed is slower than necessary when mixing just to hydrate the flour prior to the addition of the oil.

[Re: When to add the oil 1232](#)

Partially opening the dough using a sheeter or rolling/pastry pin and then finishing the opening process by hand to full diameter is a procedure which we developed a good number of years ago as a teaching aid for those who were deemed to be "toss challenged". The process is now used in a number of pizzerias. I have a video on the process. If you would like to view the video just send me an e-mail at <thedoughdoctor@hotmail.com> requesting the video and I'll be glad to send it to you. The procedure is also very useful when one is having a problem opening the dough by hand and continually getting a very thin center section to the opened skin. We've discussed this procedure many time here in the past.

[Re: Naughty words - dough roller...and hydration rates...1233](#)

Actually, the dough really doesn't look to be all that bad. The reason for the dough being soft and a bit sticky is most likely due to the use of an all purpose flour. There is no standard to which all purpose flour is held such as there is for bread and pizza type flours. All purpose flours can contain anything from a low of 9.2 to as much as 11% protein content, even worse we have found that some all purpose flours are made from varieties of soft wheats as opposed to the more commonly used hard wheat varieties. My standard (go to) flour is a strong bread type flour with 12 to 12.8% protein content. You are correct in assuming that vegetable oil can be substituted for the olive oil with the only difference being in flavor.

[Re: Dough Doctor's Basic Dough Recipe1234](#)

Just an observation, 0.3% IDY and 3% salt is a bit of a mismatch for optimum yeast performance. There is a distinct possibility that the high salt level is suppressing the yeast activity/fermentation enough to affect the oven spring characteristics of the dough. A quick test for this would be to re-run the dough but reduce the salt to 2% to see if that improves the oven spring characteristics.

[Re: poor oven spring/texture after 3 day ferment1235](#)

Whole-wheat dough = 100% whole-wheat flour.

Wheat dough = any blend of whole-wheat flour and white flour.

Most people find it a lot easier to make a wheat crust than a whole-wheat crust but you can make a pretty decent whole-wheat crust if you want to go to the effort of finding the correct dough absorption to use for your specific whole-wheat flour.

[Re: King Arthur Whole Wheat Flour Dough1236](#)

The addition of any kind of fat to the dough formula will go a long ways towards making for a more tender eating crust, but what struck my interest was your comment on how the dough just gets more sticky as you allow it to rest/ferment

(did I read this correctly?). If this is indeed the case you might be dealing with a flour with a high level of starch damage. There is just no way you can ferment a dough made with a high starch damage flour for more than an hour or so. You might look around to see if you can find a similar flour to that which is being used by Greenwich Pizza/Jolibee Foods Corp. The flour they had been using was made from U.S. hard red spring wheat milled there in the Philippines.

[**Re: Tough cornicione/pizza**](#)**1237**

The stickiness you noted is not due to damaged starch, instead it is due to unabsorbed water in the dough. The bran is slow and difficult to get fully hydrated and until it absorbs its share of the water the dough will be sticky. The best way to get around this is to use an autolyse (whole-wheat flour + all of the water) and allow this to set for at least 1-hour. If you do this in the mixing bowl all you need to do is to add the remaining dough ingredients and carefully incorporate at low speed for a minute or so, then complete the mixing process at a higher (medium) speed. The finished/mixed dough SHOULD feel tacky but not overly sticky. I think your observation on the fermentation of your dough was due to the dough becoming stiffer as the bran continued to hydrate during the fermentation process. If you are planning to allow the dough to ferment much more than 1-day you might want to think about providing some nutrient for the yeast in the form of adder sugar (1 or 2%) or 0.25% of a 20L diastatic malt powder). If your yeast is running out of nutrient to feed upon adding more yeast will just make matters worse.

[**Re: Neopolitan with Stoneground**](#)**1238**

We have had significant discussion here on how to determine the absorption of whole-wheat flours, if you read back in the archives you should be able to find the procedure. Just a tip, the dough absorption of a whole-wheat dough will be close to 75% due to the delayed absorption properties of the bran.

[**Re: King Arthur Whole Wheat Flour Dough**](#)**1239**

The reason for developing the dough until it develops a smooth skin is to reduce the stickiness and amount of dusting flour required during the scaling and balling (rounding) process. Even at that level of gluten development the dough is still far from fully developed so there is little or nothing to be gained from mixing it any less. If you want to optimize an open cell structure you should concentrate on optimizing the dough absorption for the type of pizza you're making as well as the baking characteristics of your oven. For a less chewy finished crust I suggest using a lower protein, bread type flour with a protein content in the 12 to 12.8% range in conjunction with 48 to 72-hours cold fermentation time.

[**Re: Mixing Times**](#)**1240**

Your question is impossible for me to answer as I don't know anything about your flour, type of dough agitator, dough size/amount of flour used or dough formulation all of which will impact dough mixing time, and then for good measure let's add ability of the mixer to mix whatever the dough size is at a sufficiently high R.P.M. (stir) is not it, so I'm guessing you're either mixing at too slow of a speed or the mixer doesn't have enough Oomph to do the job at a higher speed with your dough size. All of that aside, you should be mixing your dough at something between 115 and 125 R.P.M. if you are trying to develop the gluten mechanically, at that speed it should take 8 to 10-minutes to achieve the desired smooth appearance (this is assuming you have a reverse spiral dough arm, if you have a straight "J" hook or "C" hook you will need to go to about 150 R.P.M. to get the dough to come off of the hook for decent mixing action.

May I suggest an easier mixing method?

Put water in mixing bowl.

Add salt and sugar (no need to mix).

Add flour and yeast (yeast on top of the flour unless ADY).

Mix at low speed just until you don't see any dry flour in the bowl, then add the oil.

Mix one more minute at low speed after adding the oil.

Mix at the highest speed possible (see above) until a smooth skin is developed on the dough.

Measure the dough temperature (70 to 75F).

Scale and ball.

Lightly oil.

Refrigerate 24 to 72 or more hours.

[Re: Mixing Times](#) **1241**

Yes, but the perceived saltiness is greater due to the "pretzel effect".

[Re: Brine percentage](#) **1242**

ADY, IDY and CY all smell the same after the ADY and IDY have been hydrated BUT keep in mind that it is perfectly NORMAL for CY to have the aroma of a very well used diaper pail (think of the wonderful aroma of ammonia), this can happen if the yeast hasn't been sufficiently washed prior to centrifuging and packaging. The manufacturers seem to pay a little more attention to this with their home consumer packages than they do with their 1-pound packages intended for the commercial baking industry. And above all, don't forget that it isn't the aroma of the yeast that provides those wonderful aromas and flavors in our baked goods, it's the by-products of the fermentation process combined with the baking process that are truly responsible for all that good stuff.

[Re: Cake yeast ?](#) **1243**

Very high absorption doughs are better hand mixed than machine mixed, the reason being that the high absorption doughs are so slack (soft/fluid) that it is difficult to get consistent gluten development unless special mixing attachments are used. Some home bakers will use a flat beater aka paddle to mix the dough until a reverse spiral dough arm can be used to complete the mixing process. As for incorporation of air during the mixing process it's about the same for both hand kneading and machine mixing. The reason why we often see those large bubbles in the hand kneaded dough is because the dough is actively fermenting during the kneading process, it's not the air that's being incorporated. Many home bakers of both bread and pizza like to machine mix the dough to a point where it comes together and then finish by removing the dough from the mixing bowl and hand kneading.

[Re: Flour, water, salt, yeast - Quick question](#) **1244**

All ingredients are calculated as a percent of the total flour weight.

Here's how its done:

using your calculator;

1) Enter the flour weight.

2) Press "X".

3) Then enter the ingredient percent you want the weight for.

4) Then press the "%" key.

5) Read the weight of the ingredient in the display. The ingredient weight will always be given in the same weight measures that the flour was shown in.

[Re: Basic hydration calculation](#) **1245**

I use 1.75% salt in the dough (bakers %) and all of the brine solution goes onto the fully proofed dough after making a series of finger pockets to hold little puddles of the brine, then very lightly sprinkle with a little flake salt or sesame seeds.

[**Re: Brine percentage**](#)**1246**

If you have ever made bread at home and had it collapse, even partially collapse in the oven, you might have noticed that the finished bread had a crumb structure that was similar to some form of an art gum eraser in the making. The open porous crumb structure allows for effective moisture migration towards the heat (the oven air) while a more dense crumb structure restricts the migration of moisture resulting in a higher moisture content in the finished product. So when the bread dough cited above collapses it becomes more dense and retains more water/moisture in the finished product, in many cases this can dramatically change the entire character of the crumb structure. This is also one of the reasons why when a dough is opened 100% by sheeting, be it by machine or rolling/pastry pin, it is more difficult to obtain a finished crust that is as crispy as that from a dough that was opened by hand, and in many cases the crust formed by the sheeting process may not retain its crispiness as well as a hand opened dough. This is why in many cases we allow a skin formed by the sheeting process to proof for a few minutes after forming as this allows the dough to develop a better internal cell structure which is more conducive to removing moisture during the baking process.

[**Re: Correlation between hydration and cook temp and time**](#)**1247**

It was applied to 500-grams of focaccia dough.

[**Re: Brine percentage**](#)**1248**

The auction closed this evening, Hobart N-50 mixers went for just over \$500.00 each and Hobart A-120 mixers went for just a tad more. The Hobart HL-200 mixers went for around \$3,000.00 each. Attachments for all sizes of mixers went REAL cheap as

did stacks of Lloyd Pans (many were brand new) which sell for \$25 to \$40.00 each. Hobart M-820 mixers went for about \$5,000.00 each which is a real deal considering they were like new and that's what a used one (a well used one) was selling for 10-years ago. The Marsal deck oven went for about \$1,800.00 and an XLT and Middleby-Marshall WoW (both air impingement ovens) went for a little over \$3,000.00, not a bad price for low mileage ovens. Pizza tools like dockers, cutters, Equalizers, etc. were nearly give aways as they were sold in groups.

The end of a 100-year era! :'

[**Re: Equipment from AIB is now for sale online.**](#)**1249**

With doughs in the 56 to 68% absorption range it is all done as a single step but with high absorption doughs (over 70%) allowing the dough to rest for about 10-minutes usually helps in shaping the dough.

In most references where they mention "rolling the dough" they are actually referring to the balling of the dough so depending upon a host of factors the rest period between rolling and opening can be anywhere from something measured in minutes to hours. In bread production this rest period is commonly referred to as "intermediate proofing". When making pita or Barbari the rest period is usually around 20-minutes.

[**Re: Missing link?**](#)**1250**

Peter;

You found it! It's the May, 2011 article.

I'm looking for the location of the Lost Dutchman's Gold Mine, can you see if you can find it for me? :-D

Man! You're good!

[Re: Brick oven temp?1251](#)

Nope, doesn't work that way, the lower the absorption the denser the dough is during baking due to restricted oven spring so it doesn't bake out as well hence requiring a longer baking time at a lower temperature.

[Re: Correlation between hydration and cook temp and time1252](#)

Peter;

That's not the article I was referencing but it's still a good article ^^^

I wrote that one after I had been contacted by a number of new operators who had bought used ovens and couldn't get them to bake a decent pizza (hence my closing comments). In one case the individual had an oven that was sold to him as a "pizza" oven but tracing the serial number back to the manufacturer showed that it had been built for a major seafood chain and it was still equipped with the proprietary seafood finger profile which looked nothing like a pizza profile. If I remember correctly I think I wrote the article for my column in Pizza Today Magazine.

[Re: Brick oven temp?1253](#)

Andy;

I wrote an entire article on this very topic some time ago as too many people don't choose the oven based on their store concept.

DELCO (delivery/carry out) pizzas need to be as dry as possible to reduce deterioration in the box due to excess moisture from the pizza toppings. Deck ovens are very poor at removing excess moisture from the top of the pizza as they have no forced airflow, air impingement ovens, on the other hand, can be set up/top profiled to provide the maximum amount of airflow to the top of the pizza for maximum/optimum dryness thus reducing the amount of steaming the pizza is exposed to in the box. Additionally, there is no chance of short baking a pizza during busy periods which can result in a tough, chewy pizza. To further address the chewy issue we have found that the use of a lower protein content flour (11.8 to 12.4% range) is also helpful in reducing the perceived toughness when the customer receives their pizza.

[Re: Brick oven temp?1254](#)

Take note: There is still some time left to bid on auction items, I was just there <www.equip-bid.com/auction/6096> and there are scads of pizza pans and screens, the pans are mostly Lloyd Pans with an average value of \$25.00 each right now bids are in at less than the cost of a single pan!!! Looks like Hobart 20-qt, bench top mixers went for around \$2,000.00 each and 12-qt mixers for around \$500.00 each.

Some really sweet deals there.

[Equipment from AIB is now for sale online.1255](#)

What do you hope to achieve by a faster bake time? Remember that longer baking times help to develop a crispier pizza crust and also help to develop more crust flavor. If you want to have a buttery flavor why not use Butter Flavored Crisco? Works great!

Let's streamline your process:

Put water in mixing bowl, add salt and sugar, add the flour and Butter Flavored Crisco then add the yeast (you didn't mention it but I'll assume you using it). Mix at low speed for 2-minutes then at medium speed for about 8-minutes or JUST until a smooth dough is formed.

Your desired finished dough temperature range should be 75 to 80F.

Take the dough immediately from the mixer to the bench for scaling and balling.

Place dough balls into dough boxes and lightly oil the top of each dough ball.

Immediately place in cooler cross-stacked for 2-hours or until the INTERNAL ball temperature reaches 50F, then down-stack and place a lid on the top box.

Allow to cold ferment for at least 24-hours (48-hours is better).

If dough is properly managed it will be good for up to 72-hours in the cooler.

To use, remove dough from cooler, allow to temper AT room temperature until the INTERNAL dough ball temperature reaches 50F, the dough balls are then ready to be opened into skins by your preferred method. Once you begin opening the dough balls they will remain good to use for up to 3-hours so be sure to pull only what you will need out of the cooler for not more than a 3-hour period.

Any dough not used in the 3-hour period should be opened, put onto wire pizza screens and placed into a wire tree rack in the cooler (cover with a plastic bag to prevent drying) and used during the next busy period. To use the pre-opened skins, remove from the cooler 20-minutes prior to use, remove from screen, re-stretch if necessary, dress to the order and bake. Do not save the opened skins from one day to the next.

Any unused opened skins can be added back to fresh dough at a rate not to exceed 15% of the fresh dough weight.

[Re: Brick oven temp?1256](#)

At anything above 70% I always use an autolyse (1-hour) and due to the very fluid nature of the dough the mixing time will be relatively long to get any gluten development in the mixer. With all of this being said, you should really be posting to Craig as he is the one most familiar with his dough formula and procedure.

[Re: 80% HD question1257](#)

I have personally never made a Detroit style pizza with more than 68% absorption, more typically I will use something closed to 65% depending upon the absorption characteristics of the flour I'm using at the time. I'm not familiar with Craig's Detroit dough formula but I see your notation regarding the flour. How does the KAAP flour differ from what Craig's formula calls for using? Flour is usually not one of those "one size fits all" things so using a different flour can really upset the apple cart. I don't know if that the case here or not.

Also, did you take into account the water content in the starter when calculating the dough absorption, if not that would have added about another 7% water.

[Re: 80% HD question1258](#)

We used to use 5-grams of salt in 90-ml of 100F/38C water, so your proportions are very close to what I've used in the past. We used to also sprinkle the dough with flake salt too.

[Re: Brine percentage1259](#)

Something between 500 and 550F should work well for you. All ovens are a bit different so you will need to experiment a little to see what temperature works best for your specific dough formula and dough management procedure. Hopefully you are planning on a dine-in with some DELCO as opposed to a DELCO store only in which case an air impingement oven would be a much better oven choice.

[Re: Brick oven temp?](#)**1260**

Generally speaking, higher dough absorption performs better with higher baking temperatures and there comes a point where it's essentially mandatory or the dough will collapse in the oven when it should be experiencing oven spring. Lower absorption doughs are usually best baked at lower oven temperatures. Dealing with deck ovens a lower temperature means 450 to 525F and a higher temperature means 550 to 650F and more. Many deck ovens will not reach a sufficiently high temperature to effectively handle the truly high absorption doughs which will require a baking temperature of 700 to 900F. As the dough absorption rises the dough becomes softer and more extensible so it rises faster and a little sooner during the oven spring stage of baking, this is why you are seeing a more open cell structure, you should also get a more tender eating crust which is more crispy too. As opposed to many home ovens, any commercial oven should bake a better pizza at comparable temperatures due to the greater heat/temperature recovery of the commercial oven resulting in the pizza baking at a more constant temperature than non-commercial ovens which in many cases lack decent heat recovery, this is especially evident when baking multiple pizzas back to back.

[Re: Correlation between hydration and cook temp and time](#)**1261**

Yes, using a malted flour would allow him to reduce or eliminate the sugar but since he is using so much sugar I'm assuming he likes the sweetness imparted by the sugar and he'd lose that if he reduced or eliminated the sugar. The "00" flour and 460F are not an issue due to the sugar helping with the browning reaction.

[Re: Cook times and temps](#)**1262**

The AIB On-Line Auction is still in progress. In anyone is located within a reasonable driving distance to Manhattan, Kansas you might want to take a look at the equipment which is for sale which includes mixers (right now there is a Artofex Twin Arm Dough Mixer which emulates hand mixing with a \$250.00 bid on it). There are also MANY 12 AND 20-quart Hobart mixers as well as larger mixers too. It looks like much of the pizza equipment is on pages 12 and 13 of the listing. To view the auction go to <www.equip-bid.com/auction> 6096 (you may need to go into the current auctions to find it as I did). The auction closes on 11/25.

[Equipment from AIB is now for sale online.](#)**1263**

Pizza dough should not be sticky, it can be soft, very soft but not sticky. I have no problem peeling a pizza made on a 72% absorption dough into the oven using fine grind corn meal under it, I've done higher but seldom do I venture into that territory anymore. A common cause of a sticky dough is excessive diastatic malt or in some cases excessive fermentation, if neither of these seems to apply in your case try using an autolyse (1-hour) in your dough mixing procedure, it can help a lot.

[Re: Putting pizzas in the oven without a peel or screen in a pizzeria?](#)**1264**

OK, let's start at the beginning, first you will need to WEIGH all of your ingredients, no more portion amounts (cups) as different individuals portion your ingredients differently, but 100-grams is ALWAYS 100-grams, regardless of who might weigh it.

Next, you're using the delayed oil addition mixing method but you are adding the oil way too late in the mixing stage, instead, mix the dough for just 2-minutes at low speed and then add the oil, mix one more minute in low speed and then mix

8-6-minutes in medium speed. Forget the window pane test, it's used only for bread making, not pizza as it is used to determine gluten development and we really want to MINIMIZE gluten development when making pizza dough. As soon as the dough has a smooth appearance it is done mixing.

Measure and record the finished dough temperature.

Take the dough directly to the bench and immediately begin scaling and balling the dough (this must be accomplished within 20-minutes or less of completion of dough mixing).

Lightly oil each dough ball and place into the fermentation container, take it IMMEDIATELY to the cooler (uncovered for 3-hours), then cover for the duration of time in the cooler.

When ready to use the dough remove from the cooler 2-hours before you open the dough balls into skins using your dough sheeter/roller.

Prepare the pans by greasing with Crisco.

Fit the sheeter dough piece into the greased pan(s).

Allow the pans of dough to rest at room temperature for 30-minutes (this time may be varied depending upon desired final crust thickness).

Cover the pans of dough and place in the cooler for storage until needed.

Give this process a try, it should provide a much greater level of consistency to your product.

[Re: Cook times and temps](#) **1265**

Peter;

I was once told that "perception is reality and reality is just a perception", perception and reality don't always go hand in hand though. You're right, blowing under a pizza to help release it from the peel is perceived as one thing (almost like coughing on the pizza to some) while blowing out birthday candles on a cake is yet another thing entirely (in this case the cake is more dangerous than the pizza due to lack of a post "blowing" kill step which the pizza will receive. Then too, how many times have you seen someone wipe their hands on an apron or towel tucked into the apron ties (think Emeril Legasse), and then handle your food? BAD IDEA! Most people never give it a second thought but if you're in food safety it makes you cringe. Fifty years at AIB taught me a lot about food safety, but reality has taught me if it doesn't kill me it will only make me stronger, now if we can just convince our customers of that.

[Re: Putting pizzas in the oven without a peel or screen in a pizzeria?](#) **1266**

In reviewing your attached material I'd venture a guess and say that pizza might not be permitted. However it should be very easy to get a final word on this, just contact the authorities and ask them about how they view pizza. While a plain cheese pizza is one thing that they might allow without refrigeration one with meat and or vegetable toppings is yet another. If you were to have an oven in which you would heat the pizza slice to a temperature above 160F (minimum temperature for a "kill" step) this might influence their opinion in a positive way for you.

[Re: Cottage industry question](#) **1267**

The "blowing trick" while effective, doesn't always set too well with the customers in a pizzeria operation.

[Re: Putting pizzas in the oven without a peel or screen in a pizzeria?](#) **1268**

Peter;

It's interesting to note that the reason why I mentioned the Calumet brand baking

powder is because it is one of the few that is based on soda and SALP (sodium aluminum phosphate). This is important as SALP has a slower reaction rate than the other food acids so it functions more like yeast in reaction rate rather than reacting very fast as many of the two stage baking powders do. It's also interesting to note that the residual acid component has a significant impact on finished crust flavor, SALP imparts what we call a "biscuit" like flavor (due to the use of SALP based leavening systems in biscuit mixes) that's why we associate the flavor with biscuits, then there is GDL (glucano delts lactone), the residual GDL imparts a decided sweet taste to the crust, and SAPP (sodium acid pyro phosphate) is the leavening system of choice for use in cake donuts, in fact the flavor of a cake donut is that of SAPP. The next time you eat a cake donut run your tongue across the back of your teeth and you'll feel a roughness, this is a phosphate coating from the SAPP. Due to health concerns in Europe SALP is not on the approved food ingredient listing (it doesn't have an "E" number), so CAPP (calcium acid pyro phosphate) is used as a replacement. Aluminum is the issue, at one time aluminum was thought to be associated with Alzheimer's Disease but that was disproved many years ago. CAPP has not been widely available in the U.S. due to the availability of SALP and since they both perform in a similar manner why have two products? We are beginning to see more applications of CAPP though in specialized products where the biscuit like flavor is not desired so if you happen to see CAPP in the ingredient declaration this is the reason. We use SALP in the WRISE product because the biscuit like flavor imparted by any residual SALP is the least offensive in a yeast leavened product. With that said, some refrigerated doughs are made using GDL with the reason being the superior stability offered by the GDL over all of the other food acids. When you have a dough system that is 100% chemically leavened and the chemical leavening system is based on GDL and soda it is incredibly stable until it goes into the oven, the biggest down side to GDL is its low neutralizing value so you need to use significantly more of it to get the same performance you get from SALP and SAPP which in the end means a higher formula cost. In short, when you see GDL being used there has to be a very good reason for using it.

[Re: Baking powder dough?1269](#)

That article sure brings back memories. :)

[Re: Baking powder dough?1270](#)

If you are making doughs infrequently during the day and have concerns over any dough in the bowl drying out (your 5-minute time limit doesn't suggest this though) all you need to do is to use a flexible plastic bowl scraper to scrape down the bowl after each dough.

[Re: Properly cleaning a spiral mixer with non-removable tub?1271](#)

One of the biggest problems with using baking powder along with yeast is that the soda portion of the baking powder (BP) is neutralized by the acids formed during the fermentation period which results in the acid component being left without any alkali (soda) to work with. This results in a lighter finished crust color and depending upon the food acid used in the baking powder a "different" finished crust taste. In commercial practice a combination of both yeast and chemical leavening can/are used (examples include DiGiorno Frozen Pizza as well as many popular take and bake pizzas) BUT plain BP is not used, instead a coated/encapsulated chemical leavening is used. The trade name for this product is "Wrise" manufactured by Wright Enrichment Company. For home pizza makers you can make a version of this product by using Calumet Brand baking powder and regular Crisco. Use 2% BP and an equal weight of Crisco and work together VERY

WELL in a small bowl using a table fork. The fat encapsulates the soda portion of the BP and prevents it from going into solution thus preventing it from reacting with the acids formed during fermentation until the fat is melted in the oven at which time it reacts to give enhanced oven spring. I've got a number of dough formulas for these combination leavened doughs posted in the RECIPE BANK at the PMQ web site <www.pmq.com>.

Flavor wise, 100% chemical/BP leavened crusts leave a whole lot to be desired flavor wise, reminds me of the old Chef Boyardee Pizza kits that we had when I was a kid back in the early 50's, empty the bag of dough mix into a bowl, add warm water and mix, allow to rest a few minutes, spread onto a cookie sheet, add the sauce and cheese and into the oven it went.

Re: Baking powder dough?1272

Huh? Unless you're making VERY different doughs there is absolutely NO need to wash a mixing bowl between doughs. What is the reasoning behind this?

Re: Properly cleaning a spiral mixer with non-removable tub?1273

Just pour in some very hot water (amount will vary with size of your mixer) no soap is needed. Cover bowl with a sheet of plastic and allow to steam for 15 to 30-minutes, then scrub using a plastic bristle pot brush, bail out the water and add clean warm water (100F+/-) to rinse, then add some sanitizer and wipe down.

Re: Properly cleaning a spiral mixer with non-removable tub?1274

If you are using your regular flour for a peel dust you might try using fine corn meal, semolina flour, rice flour, my personal favorite is a blend of equal parts of fine corn meal, semolina flour and my regular pizza flour.

There is also a little "knack" to peeling pizzas into the oven. You will want to shake the peel just before dressing the skin to make sure it's still free from the peel, then shake it again after dressing the skin (better to know the skin is sticking to the peel before the oven surprise).

One more thing, it's common to open the skin on the table and then pick it up and transfer it to the peel for dressing and peeling it into the oven as opposed to opening the skin right on the peel.

There has been a lot of discussion on how to peel a pizza into the oven here.

Re: Putting pizzas in the oven without a peel or screen in a pizzeria?1275

With that level of IDY in a biga that is fermented for 15-hours at 70F room temperature, plus the fact that the biga is increasing in temperature due to heat of metabolism the flour in the biga has been pretty well damaged by enzymatic activity as well as the acids formed by the fermentation process. For this reason I would not include the flour in the biga as part of the total flour. This is the same thing we do with a sour. It is impossible to tell just how much of the flour is still viable but my best guess would be 0 to 20% at the very most.

Re: Biga percentages1276

Maybe she's of the opinion that only DEPLORABLES shop at Walmart? WM meats are what is referred to as "previously frozen" which some think of as not as good as fresh, Like you I see no difference. When we're shopping for steak (which is rare since we eat mostly venison), our "yum" factor doesn't even begin to kick in until we see a cut of meat that is over 1.25-inch in thickness. Many of the WM cuts are, in my opinion, too thin (to control the cost), my wife bought one of those 3/4-inch thick steaks many years ago and it is still serving me well as a replacement sole on one of my hunting boots, needless to say we didn't shop WM for meats again for

several years, then we found that WM also carries thick cuts too (just like our local supermarket) so we tried it and it was as good as what we were getting from the supermarket as fresh meat.

[Re: Walmart meat](#) **1277**

The pivotal question is how long are you fermenting your biga?

[Re: Biga percentages](#) **1278**

Here you go;

DOUGH: (In bakers percent)

Flour: 100%

Water: 65%

Poolish: 20%

Salt: 3%

Oil: 2.5%

IDY: 0.5%

POOLISH: (In true percent)

Flour: 49.76%

Water: 49.76%

IDY: 0.466

Note: While the above percentages should total 100% due to rounding the actual total is 99.986% (close enough for our work).

I have no idea of what your dough ball weight will be so you will need to do it yourself, here's how to do it.

- 1) 4 X desired dough ball weight = calculated dough weight.
 - 2) Add 5% for dough loss = ACTUAL dough weight.
 - 3) Add up the bakers percents in the dough and divide the sum by 100.
 - 4) Divide the actual dough weight by #3 above. This will give you the new flour weight needed to make your 4 dough balls.
 - 5) Calculate each ingredient weight using bakers percent and your new flour weight. (ingredient percent X flour weight, press the "%" key and read the ingredient weight in the display. Note: Ingredient weight will be in the same weight units as the flour is shown in).
 - 6) Repeat this for each ingredient and the dough has been completely resized.
- Now for the POOLISH:
- 1) Using your calculator, enter the calculated poolish weight for the resized dough, then enter 49.76 and press the "%" key, read the amount of flour needed for the new poolish in the display.
 - 2) Enter the calculated poolish weight for the resized dough, then enter 49.76 and press the "%" key, read the amount of water weight for the new poolish in the display.
 - 3) Enter the calculated poolish weight for the resized dough, then enter 0.466 and press the "%" key, read the amount of IDY to be added to the new poolish.

DONE!

[Re: Large dough recipe:](#) **1279**

Try 2-hours before balling the next time, I think you'll get a better dough.

[Re: My biga dough ball is big and lumpy](#) **1280**

I don't understand your question about oiling the shells? Are you making par-baked shells too? Need more details on that one in order to answer.

The dough weights you are showing for the different size pizzas (are they all for the same type of pizza?) are all over the board weight wise for the sizes. Of the three sizes (10, 14 and 16-inch) and the weights shown for each 10, 18 and 23-ounces) which diameter and dough weight represents your best pizza? With this information I can calculate the dough weights for each of the other sizes.

To give you the desired dough temperature for YOUR dough I first need to see your entire dough management process, beginning to end, complete with all times and temperatures.

In view of your circumstances, I suggest that you please give me a call so that we can discuss some of this over the phone.

Please feel free to call me at 785-537-1037 (please e-mail me with date and time at <thedoctor@hotmail.com> we are in the central time zone).

Re: Yeast enough?1281

Here's what your dough formula looks like in bakers percent;

Flour 100% (800-ounces)

Yeast 0.625%

Sugar 2.125%

Salt 1.125%

Oil 1.625%

Water 57%

How it's done: Divide the ingredient weight by the total flour weight (800-ounces in this case) and multiply by 100.

Example: Yeast/ 5-ounces divided by 800 X 100 = 0.625 (0.625%)

Do this with the weight of each ingredient and you should get the same numbers that I got.

See, wasn't that easy? :-D

What am I looking at here?

Yeast: Too high for IDY and too high for ADY and too low for CY. What kind of yeast are you using?

Sugar: The percentage looks OK if you're using a deck or air impingement oven.

Salt: At 1.125% the salt level is too low for optimum flavor in the finished crust and the low salt level might be working against you if you are using ADY or IDY because low salt and high yeast makes for fast, uncontrolled fermentation rate.

Oil: Typical range for oil is 1% up to 10% (more typically 2 or 3% at the high end) nso the oil is OK.

Water: The dough absorption is 57% which would indicate that you are trying to make a thin crispy or pan style pizza. Typical dough absorption for this type of pizza ranges from 56 to 63% but there can be a lot of variability in dough absorption.

Possible issues experienced with a dough formulated such as shown;

Possibility of blown dough.

Once dough is ready to open it doesn't last very long due to over fermentation.

The dough might feel sticky in the mixing bowl and during the scaling/balling process.

Finished crust lacks "something" in flavor. Some might describe the flavor as "starchy" which is common for a low salt product.

Note:

Are you measuring and recording the finished (mixed) dough temperature for each dough you make? This will have a great impact on how the dough ferments. Unless the inside temperature of your shop is varying with seasonal changes if you control the finished dough temperature you will get the same rate of fermentation all year long, and even if your shop is 10 to 15F cooler or warmer due to seasonal changes controlling the finished dough temperature will eliminate much if not all of the temperature variation. Lastly, you are making doughs based on 50# of flour weight which means you are scaling and balling upwards of 83# of dough at a time. You must be able to get the entire dough processed (scaled, balled, boxed or bagged, and in the cooler) within 20-minutes. Are you achieving this? If not you are introducing a level of variability that most pizzerias find unacceptable.

We can work with you to address these issues.

[Re: Yeast enough? 1282](#)

The dough looks to be a bit under mixed. Did you mix it until it developed a smooth skin?

[Re: My biga dough ball is big and lumpy 1283](#)

It looks like it was cut from the top down? Or was it cut when still very hot which caused the cheese and toppings to draw down over the cut area obscuring much of the view of the crumb structure?

Also, see if you can get a picture up close.

[Re: Air Bubbles 1284](#)

Fermentation is a very important aspect when it comes to the dough, it both directly and indirectly affects the flavor of the finished crust and it has a significant impact upon how the dough handles and bakes too. This is why short fermentation times are not all that popular when making pizzas, especially if a flavorful crust is desired. Fermentation times of 8 to 12-hours can and certainly are employed when making pizza crust but the flavor really isn't all that spectacular, but than again it all depends upon what you're looking for in the crust. If you just want "pizza" you can make an emergency dough and be eating pizza within two hours of starting the mixer but if you want something a bit better than a "belly stuffer" it's going to take a bit longer. Unless a dough reducing agent is used in the dough as an ingredient (PZ-44 or dead yeast) short fermentation time doughs will tend to be more elastic than those made using a longer (24-hours +) fermentation time.

When it comes to fermentation you can get different flavors from room temperature fermentation than what you get from cold fermentation so the two processes are not interchangeable from a flavor and aroma standpoint and which one you decide to use will be based on your own personal preferences. Because commercial bread is made using what might be described as a room temperature fermentation process many people equate the crust flavor obtained from a room temperature fermentation process as to being similar to that of "bread" while that from the cold fermentation process is best described as being more in-depth and complex and someplace down the road you might even want to try your hand at using a sourdough starter to develop a truly different/unique crust flavor profile resulting from the different micro-flora that are used to generate the leavening gas as well as the different acids, and quantity\of acids formed during the sourdough fermentation process.

Keep reading and learning and soon you'll be making truly great tasting pizzas and the beast part of it is that you will not have to share any of them with your tight lipped "friend"! When he comes a askin" just remind him that "what goes around

comes around", but by all means do suggest that he join the family here at Pizzamaking.com, we'll be glad to help him. :chef:

[Re: Flour vs Oil](#)**1285**

Do you have a scale or access to a scale that can weigh in ounces? If so, portion each ingredient and weigh it. Do this three times and write down the weight each time. I'll figure the average ingredient weight for you and convert your "recipe" into a dough formula based on bakers percent. It's a LOT easier to review a dough formula than a dough "recipe". You might have a hard time figuring out the amount to leave as a tip now but in short time we'll have you working in bakers percent like a math major. :chef:

[Re: Yeast enough?](#)**1286**

Vertically, bottom to top.

[Re: Air Bubbles](#)**1287**

Can you please provide us a picture of the bubbles?

The shape of the bubble is important to know. Since you are sheeting a rather cold dough (only 1-hours tempering after CF) this might be where the problem is stemming from, but I really need to see a picture of the cut surface to tell. Best way to cut the crust is to invert and cut using a razor knife or VERY SHARP serrated blade, the photograph the cut surface across the entire diameter of the pizza.

[Re: Air Bubbles](#)**1288**

What is your finished dough temperature, dough formula and how are you managing the dough?

Just for the records, 1% CY is the typical CY level used in most pizza doughs.

[Re: Yeast enough?](#)**1289**

Yael:

Your advice is "spot-on"! ^^^

I would probably want to go to something in the 5 to 10% range for added fat to the dough formula. Try using something like Butter Flavored Crisco or Lard/ bacon fat for the flavor aspect.

[Re: Sicilian Dough Chewy](#)**1290**

About 100,000 square feet of it (that's the size of the baking labs) Cake & Pastry Lab, Bread Lab., and the Cookie, Cracker & Pizza Lab.

Some of the large scale equipment was special built and designed just for AIB.

[Re: Equipment from AIB is now for sale online.](#)**1291**

Steve;

The plastic bag approach is a good one and should work well for you in this application. If it were me, I'd put them into the freezer for the first two days then transfer to the fridge for the remainder of the time, bring out, allow to warm to 50 to 60F internal ball temperature, turn out of the bag onto a floured surface and begin opening into skins.

[Re: Flour vs Oil](#)**1292**

If you want to have a hand mixed dough without getting your hands doughy it's a good mixer but if the type of pizza you're making or the dough management procedure requires a more developed dough a spiral mixer would probably be a better choice.

[Re: Dual Arm / Diving Arm Mixer](#)**1293**

I've seen that too which makes one wonder why are you putting dusting flour on the dough balls? The answer was easy once I had an opportunity to really watch the process in real time. They were not taught the advantages to cross-stacking and they knew all too well that the dough balls get wet and sticky in the dough box (in view of the fact that they are not cross-stacking the boxes) so they put the dusting flour on to help absorb the condensation which forms on the dough balls, end result is still sticky, but not AS sticky. When you oil the tops of the dough balls and cross-stack properly the end result is not sticky.

You be the judge, which method do you want to use?

By the way, to help sway you a little, there are many significant benefits to being able to cool those dough balls quickly and consistently as is afforded by proper cross-stacking. There is a reason why it is done widely practiced in places where dough failure is not an option.

[Re: Flour vs Oil](#)**1294**

That my friend is a tell tale indication of an over mixed pizza dough! The more you mix the dough the more bread like the finished crust becomes, if you want a more open, porous crumb structure you must mix the dough just until it comes together and forms a smooth skin on the surface (the smooth skin eliminates much of the stickiness associated with an under mixed dough) but if you don't mind contending with a sticky dough you can remove the dough from the mixer as soon as it comes together and begins to ball up. Many home pizza makers don't mind dealing with a sticky dough, I do it all the time (at home), but in a commercial setting it's usually out of the question as it can take too long to process and then you will have the enterprising employee(s) who will discover the benefits of copious amounts of dusting flour or oil in making the sticky dough handle better :)

[Re: Did i over work my dough?](#)**1295**

Steve;

What was the total flour weight you used?

You can do the math yourself, just divide the ingredient weight, salt in this case, (23.92) by the total flour weight and multiply by 100. If the resulting percent is over 3% the answer is yes. The typical range for salt in U.S. pizza dough is 1.75 to 2.5%, world wide it is 1 to 3%.

There are a number of things which influence the salt level used in pizza dough, here are a few of them;

- 1) Type of salt used. (It isn't the "salt" it's the sodium content).
- 2) Salt content of toppings (sauce is a topping).
- 3) Proximity to ocean/sea.
- 4) Local tastes.
- 5) Demographics of customer base.
- 6) Dough formulation, especially with regard to flour, yeast and sugar.
- 7) Environmental conditions. Think dough and fermentation temperature.
- 8) Personal tastes.

I could write a chapter in a book on this alone, probably should :-D

[Re: Too much salt?](#)**1296**

Mark;

An understanding of mixer types will tell you what went wrong.

Spiral dough mixers are designed to develop the gluten while mixing the dough, fork type mixers, on the other hand, are designed to incorporate the dough

ingredients while imparting minimal gluten development, they were actually designed to replicate hand mixing of the dough in pastry dough applications. I would suggest that you look at pulling a dough as soon as it begins to come together in the spiral mixer, record that time, and then make a couple more doughs with incrementally longer mixing times, this should give you something closer to what you are looking for.

By the way, with your dough formulation the mixing time you used in the spiral mixer should have given a pretty well developed dough structure, nothing like I would have expected from a fork type mixer using a much shorter mixing time and different mixing action.

[Re: Did i over work my dough?1297](#)

With individual containers like that you will want to oil the container too which makes removing the dough a lot easier as there isn't the room afforded by the larger dough boxes for getting a plastic dough scraper under the dough ball to facilitate lifting it out, and since there is only one dough piece in the container you don't need to worry about the dough balls clustering if the container is tipped or bumped.

[Re: Opinions on Oiling Dough Balls and Proofing Boxes1298](#)

Look for an ash content of 0.52 to 0.54% which is typical to North American high protein flours.

[Re: Flour specs like W, P/L and others1299](#)

Can you provide a picture of your pans?

[Re: Opinions on Oiling Dough Balls and Proofing Boxes1300](#)

I won't tell if you don't tell! :-D

Somebody once said "drastic times call for drastic measures", you do what ya gotta do sometimes. While you manual might have said not to use anything above speed #2 for bread or pizza dough I bet it didn't reference a 70% absorption dough in the sentence ;D

[Re: 70% hydration dough not coming together in Kitchen Aide Mixer1301](#)

It has nothing to do with time, it's all about optimizing fermentation for your specific flour. Too much fermentation results in weakening of the gluten film making it over soft and extensible and easily stretched too thin, insufficient fermentation will result in a dough that is difficult to open due to its memory characteristics (elasticity) which leads to over stretching in an attempt to get the skin to remain at the desired size after opening, this is where thin spots can again be formed. Dough which has been properly fermented will open easily with only enough elasticity to facilitate handling.

[Re: Sealing dough ball1302](#)

We normally see that happening with large capacity mixers when trying to mix doughs that are sized too small for the bowl size. The only way to address the issue is to increase the speed of the mixer, this will allow centrifugal force to pull the dough off of the agitator allowing for effective interaction between the agitator and the dough rather than allowing the dough to just go for a free ride around the inside of the bowl while clinging onto the agitator.

[Re: 70% hydration dough not coming together in Kitchen Aide Mixer1303](#)

When Googling "Manitoba wheat flour" this is what I got.

[Currently this term is used to refer to any flour that irrespective of the variety of wheat used or the production area, has resistant features similar to those of American flour. With an index of bread making capacity (W) greater than 350, the Manitoba flour is classified as a special flour]

To put it in simple terms, if you are buying Manitoba flour, you are buying someones version of an American bread type flour which will most likely be different from the domestic flours.

Kinda what we've been saying all along.

[Re: Flour specs like W, P/L and others](#) **1304**

You might try first reducing the dough absorption in 2% increments to see if that helps you open the balls without thin spots. Then try reducing the bulk fermentation to 18-hours before scaling and balling.

[Re: Sealing dough ball](#) **1305**

Enchant;

That sounds like the work of the hated "J" hook.

[Re: 70% hydration dough not coming together in Kitchen Aide Mixer](#) **1306**

Josh;

Too many people are A.R. over sealing the bottom of the dough ball. It's not necessary. The most important aspect of balling the dough is to be CONSISTENT in how you do it. I think I show it being done in one of my videos.

[Re: Sealing dough ball](#) **1307**

That's pretty close t S.O.P. Here I thought you were going to ask if it would hurt a sourdough starter in if it was taken directly out of the freezer and put directly into boiling water :-D

[Re: starter and thermal shock](#) **1308**

Just oil the top of the dough balls and you'll be just fine.

[Re: Opinions on Oiling Dough Balls and Proofing Boxes](#) **1309**

All other users combined, that's what made that statement so interesting to me. It's a lot like the Digiorno brand of frozen pizzas, at the time of my retirement, the Digiorno brand of frozen pizza had 23% of the ENTIRE frozen pizza market for their single brand, think Schwan's/Marshall Foods (Tony's, Red Baron, Freschetta) is big? They only had 19% of the market for their three flagship brands COMBINED.

Sometimes you have to take a step or two back to see just how big the picture really is.

[Re: Doctor, where is the mistake](#) **1310**

To replace 0.5% ADY with CY use only twice as much CY as ADY.

To replace ADY with IDY use 75% as much IDY as you do ADY.

[Re: Is there any problem with this dough and if yes, which?](#) **1311**

Too much oil? Yes.

Do you need to oil the box? No.

The biggest issue with oiling the dough boxes is that should the box be tipped the dough balls will cluster to one side of the box and on the following day instead of finding a bunch of individual dough balls you will find just one big old ragged dough ball. :(

[Re: Opinions on Oiling Dough Balls and Proofing Boxes](#)1312

0.25% of 20L dry malt powder is the recommended dosage for an unmalted flour.
[Re: 70% hydration dough not coming together in Kitchen Aide Mixer](#)1313

Thanks Craig, I'm familiar with essentially all of the equipment shown, you can safely consider it to be very lightly used and very well maintained (remember, AIB was a show place too). If anyone has a sincere interest in buying something and has any questions about it feel free to reference the item(s) in a PM to me and I'll try to answer any questions you might have.

[Re: Equipment from AIB is now for sale online.](#)1314

Just to weigh in here, North American flours are tailored specific to the needs/demands of North American bakers, in general it might be said that they are designed specifically for use in high speed, automated bakery operations. If a lower protein flour option is selected such as one made from varieties of hard red winter wheat (typically 10.2 to 11.2% protein content) the flour becomes more applicable to both home and small scale bakery operations however it must be remembered that essentially all bread flours, regardless if they are made with hard red spring wheat, hard red winter wheat or hard white winter wheat or a blend of them, are genetically designed to have protein properties that are strong and elastic with excellent resistance to over mixing and over fermentation, that's just the nature of the beast. When McDonalds (hamburger chain) went International I was on the Bakery Products Task Team, our job was to show local bakers/bakeries how to make a "McDonalds Bun". These buns were at first brought in frozen from a bakery in the U.S. or some other location until a specific number of stores were opened, then a large automated bakery was built specifically for the dedicated production of McDonalds hamburger buns (France, U.K., Germany, Turkey, Russia, to name but a few). In most cases bakers didn't even know what a hamburger bun was, let alone a "McDonalds Bun", and in all cases their local flours were not suited for the production/high speed production of the buns. This meant that we also had to work with the local flour mills to arrange for the correct type of wheat to be imported and milled to U.S. specifications, we were then able to work with the individual bakeries to produce the desired quality "McDonalds Buns" which were then distributed to the local McDonalds stores. As we brought more commercial bakeries on-line we didn't need to bring in frozen buns from the States anymore (damned expensive to air-ship frozen hamburger buns half way around the world). Today there is a network of commercial bakeries producing McDonalds Buns around the world with most, of them using a flour that was not even available to them back in the 1980's. Since McDonalds is said to be the second largest user of wheat flour in the world (think of that, it's pretty impressive) some countries may have started planting North American wheat varieties while others, even today, I am sure are still importing wheat specifically for this application. By the way, Weber Bros. Bakeries was the first German bakery to produce McDonalds Buns, and France was the last country that we built a bakery in and trained their production personnel before the team was disbanded. Just for the record, Australia and New Zealand were the most challenging but also the most rewarding, and Panama was the funniest by far! Czechoslovakia and Slovenia were the most interesting and scary but that's another story.

[Re: Doctor, where is the mistake](#)1315

When we studied hand mixing techniques back in the 1980's we found that the critical aspect to stretch and folds was that sufficient time was allowed between

stretch and fold session for the dough to sufficiently relax. Failure to do so resulted in the dough becoming progressively tighter with each stretch and fold session until the dough became unmanageable. The time needed for the dough to relax was variable and dependent upon flour strength, dough formulation, dough temperature and environmental temperature.

[**Re: Difference on impact from stretch and fold 1316**](#)

Your assumption is absolutely correct. In commercial bread making where sponges rule the game we do essentially this very thing by adjusting the percent of the total flour in the sponge to balance the desired dough/finished product characteristics. For example, when making white pan bread a 70/30 sponge dough system is typically used since it provides a good balance of dough handling properties and dough strength needed to withstand the mechanical shock/impacts encountered when the fully proofed dough is conveyed to the oven for baking while still providing a finished loaf with all of the desired finished product characteristics. Hamburger buns, on the other hand, are typically made using an 80/20 sponge dough process (80% of the total flour is in the fermented sponge), this is because in the production of hamburger buns a very soft and extensible dough is needed to provide the desired symmetrical shape and since the dough is not proofed to the height of a bread dough it is less prone to mechanical shock damage (generally defined as collapse) than dough used for white pan bread production.

[**Re: Poolish Experiment with Question! 1317**](#)

Peter;

Good point!

It takes about 45-minutes for whole-wheat flour to fully hydrate so both experiments should have been on an even footing BUT if the dough absorption was NOT optimized for the inclusion of the whole-wheat flour you are correct in that it might have been sufficiently low in absorption to exhibit an inhibiting effect on the rate of fermentation in the dough made with the yeast. We typically do not see much of an inhibiting effect due to low absorption when sourdough starters are used due to the nature of the bacteria as opposed to yeast cells.

[**Re: Poolish Experiment with Question! 1318**](#)

I agree with Yael in that while All Trumps flour (14+% protein content) is the gold standard for making N.Y. pizzas in N.Y.C. it is not really necessary to use such a high protein flour. When we did our pizza seminars we made great N.Y. pizzas using flours in the 12.2 to 12.8% protein range (U.S. flours). The main advantage to using a very high protein flour in this case is to achieve the desired fold ability and chew that one has come to expect from N.Y. pizzas. However, we found that today, not everyone appreciates that amount of "chew", so we are seeing more N.Y. "style" pizzas being made using lower protein flours which still produce pizzas with all of the desired characteristics but with less chew.

[**Re: Doctor, where is the mistake 1319**](#)

The picture that you've attached is that of the type of tree rack to which I was referencing.

[**Re: Best Practices for hand-stretching bases in advance ? 1320**](#)

Unless the whole-wheat flour was malted the poolish with ADY most likely ran out of nutrient for the yeast after around 6-hours while the poolish with the sourdough starter was based on bacterial fermentation, not yeast fermentation so it didn't need a source of amylase enzyme to convert starch to sugars for the yeast to feed

upon during the fermentation period. In essence you were comparing apples to watermelons since the mechanism for fermentation between the two tests/doughs is so different. The stickiness of the sourdough fermented dough was due to the acidity of the dough which breaks down the protein rendering a weaker or very poor gluten film depending upon the quality of the protein in the flour being used.

[Re: Poolish Experiment with Question! 1321](#)

The dough looks pretty good to me.

[Re: Is there any problem with this dough and if yes, which? 1322](#)

Does your KA mixer have a "J" hook or a reverse spiral dough arm? With higher absorption doughs I've found a "J" hook and spiral dough arm to be a difference without a distinction due to the small diameter of the mixing attachments. Still, the reverse spiral dough arm will perform better at developing the gluten than the "J" hook. If it will perform good enough to form a cohesive dough using your flour and dough formula remains to be seen. Keep in mind that high absorption doughs do require longer mixing times than lower absorption doughs do there is a possibility that you are just not mixing the dough long enough to sufficiently develop the gluten allowing for the formation of a dough ball in the mixer. Aside from that, you are adding a lot of malt and also a lot of sugar to the dough formula which is giving you a sweet taste in your finished crust and depending upon your oven and baking conditions, a dark crust color.

[Re: 70% hydration dough not coming together in Kitchen Aide Mixer 1323](#)

With your reach-in cooler a finished dough temperature in the 70 to 75F range will work much better for you.

[Re: Inconsistent Cook on Bottom of Pizza 1324](#)

Dry yeast: is it IDY (instant dry yeast) or ADY (active dry yeast)?

What is your water temperature?

Tom Lehmann/ The Dough Doctor

[Re: A question about Pizza dough 1325](#)

Those dough balls look really under fermented to me!

[Re: Some issues I've been having, dough rising a lot, hard to stretch, crust forming 1326](#)

What we regularly do is to open the dough balls into skins, place the skins on screens and put the screens with the opened skins into a wire tree rack and place in the cooler (uncovered for 30-minutes) then cover with a plastic bag until ready to use. To use the pre-opened skins, remove from the cooler and remove skin from the screen, dock the skin and place on a dusted peel or a baking platform, dress to the order and bake. We have used this ourselves at pizza shows and at stores where the staff gets slammed at "crunch" time. The process works quite well.

[Re: Best Practices for hand-stretching bases in advance ? 1327](#)

U.S. and Canadian flours are all milled similarly (Manitoba) I'm betting money on this, is probably a Canadian milled flour, as such it would be a hard red spring wheat variety and most likely be of high protein content, I'm guessing around 13+%. As to particle size distribution in a typical U.S. / Canadian flour the range will be from about 15 to 220-microns with most of it clustered around 100 to 150-microns in size. I have not seen any particle size distribution data on European or Italian flours so I don't know how they would compare.

You have to remember that when it comes to wheat flour it's a lot more than just protein content and particle size, genetics plays a huge part in the quality picture. U.S. and Canadian wheats have been bred for very specific characteristics (crop yield, disease and pest resistance, resistance to drought, maturity, protein content and protein quality (as it relates to stronger gluten). Other countries have different flour needs so they have developed their wheat varieties to have different characteristics which may or may not be compatible with pizza production.

[**Re: Flour specs like W, P/L and others**](#)**1328**

For anyone interested, AIB (American Institute of Baking) is selling their equipment from one of the training labs. To see the online auction go to: <equipbid.com/manhattan kansas> and look for the AIB heading.

[**Equipment from AIB is now for sale online.**](#)**1329**

I agree with Yael that 0.8% ADY is excessive for a 24-hour CF dough. The most I typically use is 0.5% but that amount can change depending upon the finished dough temperature. You also stated that the dough balls flowed together so I'm assuming (we all know what that means :D) that you're using dough boxes. I didn't see any mention of cross-stacking the dough boxes when placing them into the cooler, are you cross-stacking? If so for how long? Not cross-stacking long enough is as bad as not cross-stacking so the time is an important too. One common error associated with not cross-stacking or not cross-stacking long enough is associated with the dough blowing. To correct this the yeast is reduced (sometimes to ridiculously low levels) which addresses the blown dough but now there isn't sufficient yeast to provide the necessary leavening during the critical oven spring stage of baking which results in setting the stage for the "dreaded gum line" and a tough, chewy finished crust.

[**Re: Bulk RF vs Balled CF Need Help Please**](#)**1330**

The Alveograph is seldom used as a testing/measurement tool with American flours, with the quality of protein in these flours it really isn't necessary. To a great extent U.S. flour quality as well as dough quality characteristics are pretty well tied in to protein content of the flour. This is not the case with most European flours which are made from varieties of wheat having significantly different protein/gluten attributes so the Alveograph is much better suited to differentiating quality characteristics between different flours. You might want to do a search to see if you can find a cereal research facility such as the Canadian Grain Research Facility in Winnipeg, Manitoba, Canada. There is also a facility in France as well as in the U.K (Leatherhead), Australia also has one called the BRI (Bread Research Institute). I would think that a research facility near you with access to your local flours would be able to answer your question. As a side note: A good number of years ago France was buying a significant amount of U.S. wheat (DNS #2) dark northern spring wheat #2 (the most common exported wheat from the U.S.) U.S. Wheat Associates asked me to travel to France to survey the wheat/flour market to get a better grasp of where/how all of this wheat was being utilized. France, at the time was claiming that they had the best flour in Europe, or something to that extent. So where was a large portion of all that wheat going? Turns out it was being milled and blended into the local French flour to improve its overall baking properties and sold as French flour. I have no idea if this is still the case or not as it has been too many years since then. The point is that you might find a pretty decent flour with a lot of the DNA of a U.S. flour being marketed as domestic flour.

[**Re: Flour specs like W, P/L and others**](#)**1331**

Absolutely! Adding more water actually reduces the energy input into the dough due to the softer dough condition. When mixing pizza dough just mix it until you achieve a smooth, satiny appearance to the dough. You will find that as you continue to mix the dough it will become progressively smoother in appearance and become MUCH easier to work with immediately after mixing. Your mixing time should be in the range of 9 to 11-minutes. If you stop the mixer every 2-minutes, or so, you will be able to see the dough becoming less sticky as you handle it.

[Re: Inconsistent Cook on Bottom of Pizza](#)**1332**

The missing piece to the puzzle was the finished dough temperature. If the dough balls are expanding too much it might be due to the finished (mixed) dough temperature being too high or you are covering the containers right away as you place them into the fridge, instead, cross-stack them (just another way of saying to leave the containers open until the internal dough ball temperature reaches 50F/9.9C) this usually takes 2 to 3-hours, then proceed with covering the containers aka "down-stacking" for the duration of the CF period.

[Re: Some issues I've been having, dough rising a lot, hard to stretch, crust forming](#)**1333**

Delivery v/s dine-in pizza.

- 1) In commercial practice they are both made using the same dough as it would create a nightmare trying to use different doughs.
- 2) This is not to say that DELCO stores don't use a dough formula developed to be more compatible with the rigors of DELCO, they sometimes do.
- 3) The changes made for a specific DELCO application are to use a slightly thicker crust, think Domino's.
- 4) Lightly oil the skin prior to dressing.
- 5) Go easy on the sauce and toppings.
- 6) Use an air impingement oven as opposed to a deck oven to achieve a drier pizza.
- 7) Allow pizzas to steam off prior to boxing.
- 8) A cut pizza tends to hold up better but your customer will dictate what they want in this regard.
- 9) Boxes to have steam vents.
- 10) Ripple sheets or Pizza Savors are an asset.

Note: A lower protein content flour might benefit DELCO pizzas by reducing chewiness (#1 complaint of DELCO pizzas).

We discussed all of this not too terribly long ago.

[Re: Urban myth or truth? Different dough served in the pizzeria and in delivery](#)**1334**

OMG! Where to begin, can you share your dough formula and dough management procedure as well as finished dough temperature? And then there's the matter of the yeast, 1% IDY is waaayy too much for the average pizza dough. Instead, the amount of IDY should be something between 0.15 and 0.4% depending upon how the dough is being managed.

[Re: Some issues I've been having, dough rising a lot, hard to stretch, crust forming](#)**1335**

I forgot to add that this can also be caused by placing the pan directly on a hot deck. Place a screen under the pan for the first five minutes of the bake then complete the bake on the deck if you want to. The rapid heat transfer results in gas bubbles coalescing into large gas pockets which you are seeing, placing a screen

under the pan reduces the rate of heat transfer thus eliminating the problem.

[**Re: Inconsistent Cook on Bottom of Pizza 1336**](#)

Those are from gas pockets being formed on the bottom of the crust. Reduce the dough absorption by 3% to see if that improves the situation, if you see some improvement you might need to make further reductions in dough absorption.

[**Re: Inconsistent Cook on Bottom of Pizza 1337**](#)

Wheat as we know it and durum are two entirely different animals. The gluten formed from the durum wheat has a very tough and rubbery characteristic. The hard wheat varieties grown in the U.S. are bred for a specific purpose or characteristic. Most commonly bread making properties, yield, agronomic characteristics as well as resistance to pests and disease.

[**Re: Are American Pizzas \(New York etc\) made with hard or soft wheat? 1338**](#)

That's impossible for me to say as every flour has an "optimum" absorption. My "go to" absorption is 62% and from there I decide if I need to further increase or decrease the absorption to achieve desired dough handling and performance characteristics.

[**Re: Doctor, where is the mistake 1339**](#)

Hard wheat varieties are used for 100% of the bread and pizza flours in the U.S. Most bread flour are milled from either straight HRW (hard red winter) or a blend of HRW and HRS wheat varieties while the high protein/gluten flours are milled exclusively from HRS (hard red spring wheat) varieties. Over the past few years there has been growing use of HWW (hard white wheat) varieties in making flour but for now these wheat varieties are relegated mostly to making whole grain/whole-wheat flours. In Australia the use of HWW is almost exclusive to all types of bread and pizza flour.

By the way, All Trumps flour is the main flour used in New York and AT flour is milled from varieties of HRS wheat.

[**Re: Are American Pizzas \(New York etc\) made with hard or soft wheat? 1340**](#)

It's not the age of the oven, it's the heat/temperature in the oven that is both creating and releasing those aromas. There is a point of diminishing returns when it comes to oil and retention of those aromatics. Our research showed that 1.5% (flour basis) was the tipping point, beyond that we didn't detect any appreciable increase in crust flavor/aroma. A bunch of years ago I did work on Paradise Island, Bahamas for a locally owned pizza chain. One of the things I was asked to address was the lack of flavor in the pizzas, when addressing this all I did was to include 1.5% oil in the dough formulation and that was all that was needed to give them the flavor profile they were looking for. Sometimes things are easy, sometimes they ain't.

[**Re: The effect of yeast percentages on taste 1341**](#)

If you are having a problem with the turning peel you're probably not allowing the pizza to set long enough before moving or spinning it.

[**Re: when to add salt and oil to dough? 1342**](#)

I think I might know what's happening but first, can you please send a picture of the bottom of a pizza where this is occurring so I take a look at it? Just pop the entire pizza out of the pan and invert it then take a couple of photos of it.

[**Re: Inconsistent Cook on Bottom of Pizza 1343**](#)

Steve;

Refrigerated dough is a whole different store from frozen dough. It is most likely made in-house as it's made with IDY, the last five words in your response told me that. In any case, the dough is waaayy short on fermentation, it's not too much more than a glorified emergency dough. The next time you use it try allowing it to ferment in the fridge for 48-hours before using it. Let's see if that improves the finished crust in any way.

[Re: Store bought dough would not create crisp crust - suggestions appreciated](#)**1344**

The dough you bought was it frozen bread dough or frozen pizza dough? The reason why the dough was so easy to open is because it had a good healthy dose of a dough relaxer (used as a processing aid when making frozen dough). The dough relaxer (L-cysteine or dead yeast) are the most commonly used. Look on the package ingredient declaration to see if L-cysteine appears. If dead yeast is used it does not need to be declared separately as it is included in with the live/active yeast. Further, frozen dough has essentially NO fermentation time on it. I think this is what is causing the issue for you. To use frozen dough and get a better product try this:

- 1) Slack out the frozen dough by placing it in the fridge over night.
- 2) Remove the dough from its packaging, lightly oil it and place in a fermentation container (bowl, bag, etc).
- 3) Place at room temperature for 1-hour (make sure the dough is covered).
- 4) Place the dough back into the fridge for 24-hours to cold ferment.
- 5) Remove the dough from the fridge and allow it to warm until the internal dough ball temperature reaches something in the 50 to 60F range.
- 6) Turn the dough out of the container onto a floured surface and proceed to open into a skin for immediate use.

We developed this procedure back when we did pizza seminars at AIB and it worked quite well for us as we demonstrated the use of frozen dough to our students.

[Re: Store bought dough would not create crisp crust - suggestions appreciated](#)**1345**

I think this will help you a lot;

- 1) Adjust the yeast level to 1% compressed yeast/CY OR 0.5% active dry yeast/ADY OR 0.4% instant dry yeast/IDY. Be sure to remember to activate/hydrate the ADY prior to addition.
- 2) Adjust the water temperature to give you a finished dough temperature (after mixing) of 75 to 80F/23.8 to 26.6C.
- 3) Immediately after mixing divide the dough into desired weight pieces for the size pizza you are going to make.
- 4) Form each piece into a ball.
- 5) Lightly oil each dough ball and place into individual plastic bags (like bread bags).
- 6) Twist the open end of the bag into a pony tail and tuck it under the dough ball as you place it into the fridge.
- 7) Allow the dough balls to cold ferment (CF) for a minimum of 24-hours (48-hours is better). Experiment to find what works best for YOUR specific dough.
- 8) To use the dough, remove from the fridge, allow to warm AT room temperature for 2-hours.
- 9) Turn the dough out of the bag allowing it to drop onto a floured surface.

- 10) Open the dough ball into a skin by your preferred method.
- 11) Dock the dough skin or begin dressing the skin.
- 12) Take dressed skin to the oven for baking.

[Re: Doctor, where is the mistake](#) **1346**

Wood peels are used as a prep peel and metal blade peels are your oven peels (for removing baked pizzas from the oven).

[Re: Seasoning aluminum peel](#) **1347**

Your IR thermometer only measures surface temperature, you want to measure the internal temperature of the dough ball which is different from the surface temperature. A low cost dial/stem type thermometer is what you want to use to measure the internal dough ball temperature.

[Re: How to determine internal Dough ball temp before opening](#) **1348**

Suspending the yeast in a quantity of water and then using a portion of that water will work fine. Here are some things to keep in mind if you opt to go that route.

- 1) Make sure that the water you suspend the yeast in is 100F if using ADY or IDY. You don't have to worry about water temperature if using CY.
- 2) Remember to include the water that the yeast is suspended in as part of your dough water/absorption.
- 3) If using ADY be sure to allow 10-minutes to activate and hydrate the yeast. This is not necessary if using IDY.
- 4) ALWAYS stir the yeast suspension well immediately before you subdivide it. Here is a simple example of how to make a yeast suspension and subdividing it for a smaller yeast amount.

50-grams of water (weighed).

1-gram yeast.

Stir well to suspend the yeast in the water.

Allow to activate if using ADY.

Stir well.

Weigh desired amount.

In this case every 5-grams of the solution will provide approximately 0.1-gram of yeast, if your scale will weigh out to 1-gram accurately you are able to weight the yeast out to 0.1-gram divided by 5 = 0.002-gram.

While not as accurate as a good scale this method is plenty accurate for home use. Tip: A trip to The Dollar Store will get you a package of small, plastic communion cups that work great for weighing out small amounts of liquid, just remember to rinse the cup with the remainder of the dough water.

[Re: Yeast measurement](#) **1349**

Ditto! Tried it once and until the seasoning fully cured it was indeed worse, that's the "good" news, the "bad" news is that it seemed to take forever for the seasoning to fully cure.

[Re: Seasoning aluminum peel](#) **1350**

Q.J.:

You took the words right out of my mouth! :-D

[Re: Causes of thin spots?](#) **1351**

Most starters as well as doughs leavened only with a sourdough starter typically don't do all that well in a cold fermentation environment, and if you spike the dough with yeast the yeast will quickly become the dominant micro-organism

resulting in a loss of a lot of the flavor notes derived from the starter.

[Re: Does Anyone 48 Hour or More CF with Ischia \(or other\) Starter?1352](#)

When you open an oven in which pizzas are being baked the aroma is wonderful! Those are the aromatic compounds which are retained in the oils, even just a small amount of fat in the dough will retain these compounds, those which are not retained are lost forever which makes for a pretty good case for adding some oil to the dough formula.

[Re: The effect of yeast percentages on taste1353](#)

We've discussed this a few times before and if you ask ten different people you will probably get at least five different answers. My procedure is to begin opening the dough ball with the top side down as less dusting flour is required (more flour adheres to the rough bottom than the smooth top) and then flip the partially opened skin over to finish opening then turn it over again for docking and/or dressing. This means that the skin ends up top side down (bottom side gets dressed). In tests that we did at AIB we found that we got fewer bubbles (large bubbles), less sticking to the peel and if there was any drying of the dough ball the dry, scaly dough skin was on the bottom of the finished pizza where it posed no problems.

Note: When plastic bagging the dough there is no top or bottom to the dough ball so this becomes a moot issue in that case.

Overall, it doesn't seem to be an overly critical issue which side goes up or down as long as you're not experiencing problems cited above and you're happy with the finished pizza.

[Re: Why does the top of the dough ball become the bottom of the pizza?1354](#)

Hopefully at least 1/4-inch or thicker. Be sure to allow at least an hour for it to thoroughly heat up and if at all possible, if you have a bottom burner or heating element in your oven, move it close to the bottom heat source for the first part of the bake then move it to a higher rack position for top color.

[Re: Need More Flavor1355](#)

Remember, oil retains flavor compounds released during baking, that's why my mother always told us kids to "keep the butter dish covered in the fridge". Ever have a slice of wedding cake that tasted like a cigarette? Yep, the fat in both the cake and the icing retained all of those wonderful aromas of that smoke filled room. Try as you might, you cannot remove the flavor compounds absorbed into the crust during baking.

[Re: The effect of yeast percentages on taste1356](#)

You're already over dosed on the diastatic malt and there is no benefit to using honey over regular table sugar so my advice is to delete the honey, reduce the diastatic malt to 0.25% and add 4% table sugar then adjust as necessary. I'm guessing that the lack of browning is why you're not getting the flavor profile you're looking for. Are you baking on a stone or steel? If not how are you baking your pizzas?

[Re: Need More Flavor1357](#)

- 1) Go to 72-hours cold fermentation.
- 2) Utilize a sourdough starter in place of the IDY you are presently using.
- 3) Increase the olive oil to 2%. Try using a pomace grade olive oil as it has a more "robust" flavor.

4) Baking has a significant impact on crust flavor but you didn't provide any details so I cannot comment but make sure the crust is getting a good, solid bake with a little char if possible.

[Re: Need More Flavor](#)1358

Here is my home made hand mixed dough process;

Put 75F water in bowl

Add salt and sugar (if used).

Put yeast in a small portion of water at 100F, stir to suspend and allow 10-minutes to hydrate & activate.

Pour yeast suspension into the dough water in the bowl.

Using a wood spoon mix well to incorporate.

Scrape dough out of the bowl onto a floured surface and knead for a minute or two.

Form into a ball and place into lightly oiled bowl (I re-purpose my mixing bowl).

Allow to ferment at room temperature for 1 to 2-hours (not critical).

Turn dough out of the bowl onto a floured surface and knead several minutes just until the dough becomes smooth.

Lightly oil the dough ball and place back into the bowl to ferment for desired length of time or place into bread bag and refrigerate for 24 to 72-hours before use.

So, to answer your question, I would have kneaded it a few minutes until the dough took on a smooth appearance and placed it back into the bowl or a plastic bag (Walmart bags work in a pinch) to continue fermenting for the desired length of time.

[Re: Forgot to knead before first rise](#)1359

The yeast itself has nothing to do with it, pizzerias use the same yeast that is used by many home pizza makers, be it CY, ADY or IDY, but like other things in life, it ain't what you got that counts, its how you use it. Most pizzerias will use dough with anything from 24 to 72-hours cold fermentation time. Could they be using an inactive sourdough? Sure they could. We just recently had some discussion here on one from Lesaffre/SAF Yeast. Since dough becomes more acid the longer it ferments and acid is tart, the sweetness you mention is confusing because sweet is just the opposite of tart. You also mention "savory" which is not usually mentioned when describing crust flavor so I'm wondering if you are not being confused by possibly the flavor of the sauce which they use which might be described in those terms (sweet and savory).

[Re: The effect of yeast percentages on taste](#)1360

The real flavor/taste of raw yeast is much like that of musty newspapers. Some restaurants use frozen dough for their dinner rolls and the finished rolls have a very distinctive "yeasty" flavor owing to the fact that high levels of yeast and little to no fermentation is used in making frozen dough. What you are tuning in to are the flavors resulting from the by-products of fermentation. Buy a frozen bread dough, slack it out and make a pizza with it and you will get the same flavor profile, I've heard it likened to that of home made bread too (like Grandma used to make), that's because many home bread recipes use a lot of yeast and short fermentation times (just like that frozen dough mentioned above). It doesn't surprise me at all that you like a sourdough flavor since it's something like an exaggerated fermentation flavor. Those who like a well fermented flavor usually appreciate a sourdough flavor but those who think a well fermented flavor is like smelling a brewery generally don't appreciate a good sourdough flavor.

[Re: The effect of yeast percentages on taste](#)1361

The REALLY great thing about working in bakers percent is that it allows you to change any one ingredient (like water) without changing any other ingredient amount, so no, don't change anything but the amount of water being added to the dough. As many people here will attest to is the fact that I personally like to use individual plastic bags to store my dough in. The bags are like bread bags and can be bought at your local supermarket as food storage bags, they come on a roll and sell for only a couple of dollars. Hopefully you will have them available to you, but if not you can use any low cost, stackable, plastic food storage box with a snap on lid. Just be sure to put a couple of small holes in the lid to release pressure and then be sure to leave the lid off for the first 2-hours after placing them in the fridge, after that they can be lidded for the duration of refrigerated storage. Be sure to lightly oil the dough ball just before placing it in the box to prevent drying while the lid is off and to facilitate removing the dough from the box/bowl.

[Re: First attempt at making dough](#) **1362**

In my response cited by Peter I explained how the delayed salt addition mixing method impacts gluten development and development of a lighter dough color as well as a lighter crumb color in the finished product. While this might have validity in bread production it has essentially no validity in pizza production, the reason being that in pizza the dough is never mixed enough to achieve the oxidation by exposure to air during mixing (explained in my response) and any change to a brighter crumb color is all but impossible to distinguish in the crumb structure of a pizza crust (in bread it is easy to see, but not in a pizza crust). As for flavor, the shift in flavor is much too subtle to detect in a dressed pizza (again, bread is a different story). In my opinion, the delayed salt addition mixing method has no real value in making pizza doughs, and the greatest challenge when using the delayed salt addition mixing method whether it be for bread or any other dough application is in not having a pre-scaled portion of salt left over at the end of the production run, Oops! With all of this said, there is one place where the delayed salt mixing method IS almost universally used in dough production and that is in commercial frozen dough production (both bread and pizza). When making these doughs the absorption is minimized to some extent to help control ice crystal development in the dough and the doughs are mixed very cold (60 to 65F) with full gluten development being the objective. This means that the dough is going to be VERY tough and difficult to mix (specially designed mixers are employed) so steps are taken to help reduce the mixing time, these steps are use of the delayed salt addition mixing method as well as inclusion of a dough reducing agent such as L-cysteine/L-cysteine hydrochloride or glutathione (dead yeast) or even possibly deodorized vegetable powder (onion and garlic). This just further reinforces my observation that was responsible for me getting into pizza research back in the early 1960's, that observation was that bread and pizza technologies are very different.

[Re: when to add salt and oil to dough?](#) **1363**

It sounds like your flour might be too strong so first thing I would do is to see if you can find a lower protein/weaker flour to try. You can also experiment using your existing flour and increasing the finished dough temperature by increasing the water temperature in 5F increments. This will provide for a faster fermentation rate so the dough will receive more total fermentation within a 24/48-hours period of time. Be sure to measure and record the finished (mixed) dough temperature when doing this. The use of a "00" flour will also provide for a more extensible dough but at a higher cost. If you experiment with this type of flour, unless your

oven can get up to at least 800F/427C you will need to add at least 2% sugar to the dough formula or a small quantity (0.25%) of a 20-L diastatic malt powder, this is because the "00" flours are not malted so the yeast will run out of nutrient during the fermentation period and the finished crust will be severely lacking in crust color. Once you get the dough details worked out you can divide the dough into individual pieces, form into balls, wipe with oil and place into individual plastic bags to cold ferment (this process has been discussed here a number of times), then just remove from the fridge and allow to warm to 60F/15.5C, turn the dough out of the bag onto a floured surface and begin opening the the dough ball into a pizza skin.

One last thought, another reason why your dough might be difficult to open would be due to insufficient dough absorption. Again, using your existing flour, increase the dough absorption by 5%, this will provide a softer dough that might prove easier for you to open, again, if you need to add more than 5%, do so by all means but only work in 2% increments after the initial 5% increase. Every flour has a "sweet spot" when it comes to dough absorption so you'll need to experiment to determine what it is for YOUR flour, using YOUR dough formula, using YOUR dough management procedure, and YOUR skill set for the type of pizza YOU want to make.

[Re: First attempt at making dough](#) **1364**

Personally, I think you like the flavor from fermentation ^^. You're not alone in your preference either as most of use here have similar tastes. You will probably want to look at a 48-hour fermentation period as this provides many of the finished product flavor characteristics you have experienced. You can certainly go to a longer fermentation period too, it all depends upon personal tastes, formulation and how the dough is being managed. At some point you might want to try your hand at making a sourdough crust to see if you like that kind of fermentation flavor profile too as it is entirely different from that achieved from using commercial yeast.

[Re: The effect of yeast percentages on taste](#) **1365**

Here's what I do personally. Remove the tomatoes from the can and tear into pieces, place into colander to drain for 20-minutes +/-, add a little salt and mash slightly then apply to the pizza skin. Save the juice for the next time you make pasta.

[Re: How much of what is in the can do you use?](#) **1366**

Using the delayed salt addition mixing method is fine if you are making bread where you actually want to have significant gluten development but when making pizza dough where you DO NOT want to have significant gluten development in the dough during mixing, the salt is best added in the water for machine mixing or in the flour when hand mixing. If you are using a coarse granulation salt it should be dissolved in a small portion of the water and added soon after incorporating the flour. We don't like to add the oil to the water since it will float on top of the water and when you add the flour a portion of the flour will become oil soaked rendering an unknown portion of the flour incapable of absorbing its full amount of water and more importantly that portion of the flour which has been oil soaked will not be able to develop gluten. What this all leads up to is a greater level of inconsistency in your doughs.

[Re: when to add salt and oil to dough?](#) **1367**

For the Lloyd's pans you can dip in hot soapy water, scrub with a soft plastic bristly

pot brush, rinse and sanitize then wipe dry. For the old seasoned pans NEVER put them into water (if you do the seasoning will begin to come off like a bad sunburn and you will need to strip them back down to bare metal before re-seasoning). Just wipe out with a dry bar towel and you'll be just fine. IF you should ever need to wash the seasoned pans here's how:

Grasp pan in hand, dip in soap water, lightly scrub with a soft plastic bristle pot brush, dip in rinse, dip in sanitizer solution, wipe dry, place in oven at 350 to 400F for force dry. Please note that at NO TIME did I say to release your grip on the pan, after picking it up the only time you will put it down is when you place it in the over to force dry.

[Re: Cleaning Pans - What's the best method? 1368](#)

Two things to remember about screens.

- 1) If you are going to be baking on them ALWAYS season the screens first and then DO NOT wash them as you stand a good risk of the seasoning peeling off.
- 2) Don't proof directly on the screen as the dough can flow into the screen openings and expand during baking effectively locking the pizza to the screen. However, if you transfer the skin to another screen (this places the raised spots there the dough flowed into the screen openings off register) you can store pre-opened skins on screens and you can even proof the dough to some extent providing the dough absorption isn't too high to allow the dough to flow into the screen openings.

Screens are also great for baking bread sticks and calzones too, and if you're baking pan style pizzas in a deck oven or on a stone/steel slip one under the pan to control the bottom heat so you don't get too much bottom crust color or worse, a burnt bottom crust.

[Re: Pizza Screens 1369](#)

For sausage I like to use breakfast sausage, and for my potatoes I use frozen hash browned potatoes, crispy fried bacon bits fresh tomato slices and some cheddar cheese. They're also good with a TEX-MEX twist by using 25% Maseca Flour to replace an equal amount of white flour in the dough formula and using picante sauce for the sauce.

[Re: Breakfast Pizza 1370](#)

From the picture I would not have pressed the dough down either, I do like to pull the dough up onto the sides of the pan so they are a little thinner but that's just a personal preference. Overall, that's a good looking deep-dish pizza. :drool:

[Re: Petezaa's deep dish with semolina 1371](#)

We did it for many years. While we had some success using raw eggs we had a better product using scrambled eggs as a topping. There was a pizzeria in the Columbus Convention Center Food Court that served a breakfast pizza.

[Re: Breakfast Pizza 1372](#)

I've written a couple of articles on ovens. The air impingement ovens are by far the best ovens for DELCO shops as they give you the driest pizzas possible, deck ovens are not as well suited to DELCO as they are not as good at providing a dry pizza which is important in this application.

[Re: New User - Hot Shop 1373](#)

Do you keep a 500-gram bag or individual packets in the Mason jar?

[Re: Causes of thin spots?1374](#)

I normally use 0.375% IDY for a 24-hour cold ferment.

[Re: NY pizzeria yeast amount1375](#)

Sure you can, done it any number of times. You can also experiment with baking your pizzas on a screen and then decking them for the last 15 to 20-seconds.

[Re: Cooking lower and slower in wood fired/gas rotating oven1376](#)

Insufficient dough absorption is just another way of saying that sufficient water has not been added to the dough to make it sufficiently malleable to be opened easily. I realize that water/absorption is only part of that equation but if the absorption isn't correct for the flour being used the dough will always tend to fight you during the opening process rather than stretching out evenly for a more uniform skin.

[Re: Causes of thin spots?1377](#)

John;

Without question, those are the best scrapers for plastic dough trays/boxes.

[Re: Dough sticking to plastic tray1378](#)

I deplore metal scrapers in a plastic dough box, it has been voted as the #1 way to tear up your plastic dough boxes. Plastic dough scrapers are just too plentiful and work just as well, if not better.

[Re: Dough sticking to plastic tray1379](#)

If you are looking at ways to cut commercially made pizzas be aware that Colbourne Manufacturing makes an ultra-sonic cutter (20,000+ strokes per second) for cutting pizzas into slices or shapes without any loss or distortion of toppings or crust. All of the New York school pizzas are pre-sliced at the manufacturing facility using the ultra-sonic cutters. Additionally, some work is also being done using water jet cutting but the ultra-sonic is easier to install into an existing production line. Anything developed for the retail (pizzeria) industry will have to be low cost, effective, durable, easy to use, safe to use and easy to clean. Right now the retail industry uses pizza wheels, rocker knives of various design (The "Equalizer" by Lloyd Pans is an example of a modified design rocker knife used for cutting multiple slices at once) and even large French/Chef's knives to cut pizzas. If you should want to discuss this with me you may contact me at 785-537-1037 (let me know by e-mail before you plan to call) or you may e-mail me directly at <thedoughdoctor@hotmail.com>

[Re: New Pizza Cutter Idea1380](#)

Glad to hear that all went well, we wouldn't want to disappoint those guests! :-D

[Re: 4 day cold ferment neapolitan101](#)

Remember that you can manually round the dough to just about any level of "tightness" you want, it sounds like you have been rounding your dough loosely which is common for those who wish to use the dough balls relatively soon after rounding. Most rounders are designed to round the dough tightly, some even use two rounders in tandem, or pass the dough balls through the rounder twice as this provides for a better dough ball shape especially after several days of cold fermentation. You're not doing anything wrong, the rounder is just doing what it was specifically designed to do.

[Re: Rounder and dividers102](#)

Scott;

Yes, track/screw/cone type rounders are not well suited to handling the soft and usually sticky/tacky dough consistency associated with sourdoughs. A good alternative is a horizontal or belt type rounder sometimes called a bar type rounder. This is a horizontal belt with a specially designed bar placed diagonally across the belt. As the dough ball moves along the belt it contacts the rounding bar causing the dough ball to spin forming it into a ball, however, some oil is required with the use of these rounders. If you're interested in knowing more about this type of rounder I think AM-Manufacturing uses them in some of their high volume hot press equipment packages.

[Re: Rounder and dividers](#) **103**

Walter;

The best thing about the free standing models as opposed to the bench top models is that they can be easily rolled aside, out of the way, when not in use.

[Re: Rounder and divders](#) **104**

I can't argue with you on that! For me though, no matter how you cut it, it's still a cheese pizza! :chef:

So much for history and lore. :'(

Maybe someone can shed more light on this? ^^^

[Re: Which are the factors that affect digestibility?](#) **105**

The Marsal ovens are great ovens but they do not get as hot as a wood fired oven can. With that said, they will certainly serve you well for making New York style pizzas. Also, in New York City it is common to use All Trumps flour (14% protein content) so any good, strong Canadian flour should work well for you.

[Re: ny pizza help!!!](#) **106**

It appears as if there is too much top heat being applied to the pizza during baking. Sometimes spraying the top of the pizza (cheese) with water can help.

[Re: Cheese boiling/oiling/bubbling](#) **107**

Definitely cool it on a rack, I typically use a spare pizza screen for a cooling rack. If you don't you will just force moisture back into the baked crust and run the risk of getting a gummy crust or collapse of the crumb structure during the cooling of the crust.

[Re: Need help proofing my Sicilians](#) **108**

I didn't either, I always thought that the Margarita had the colors of the Italian flag in honor of Queen Margarita/Margherita. ???

[Re: Which are the factors that affect digestibility?](#) **109**

When you see this beginning to happen in the oven break out your handy "bubble popper" aka BBQ fork to deflate it and press it down a bit. It will also help if you cool it upside down too as this will help to flatten the top.

[Re: Need help proofing my Sicilians](#) **110**

Now I'm beginning to wonder where the green color on a Margarita came from????
Hummm :o

[Re: Which are the factors that affect digestibility?](#) **111**

You just put the IDY into about 5 times its weight of water at 95F. and remove an equal amount of dough water. No other changes are needed. Many of us already do something similar to this when we need to use just a very small amount of IDY. For example, let's say you need to use 1/10-gram IDY but your scale won't handle anything that small, what to do?? Just weigh 1-gram into a container with 10-ounces of 95F water, stir well to SUSPEND the IDY and portion out 1-ounce of the suspension, there will be approximately 1/10 of a gram of IDY in that 1-ounce of yeast suspension, just make sure you also reduce the dough water by 1-ounce too. If the IDY is unopened you will lose about 25% of the gassing power from the IDY after 2-years of frozen storage. If the package is opened all bets are off of the table. We found the best way to store IDY is to leave it in the original container, use what you need, fold the packaging down tightly to the IDY in the package and secure with tape or a rubber band. To use the next time: DO NOT use directly from the fridge or freezer!! Instead, remove from the fridge or freezer and allow to set at room temperature overnight, then use what you need and repeat the above procedure. This will reduce the probability of forming condensation in the package which is death to the IDY. We never recommended holding IDY after opening for more than 3-months (refrigerated or frozen) for home use. If you're into vacuum packaging you could break a 454-gram brick down into smaller portions and vacuum package for refrigerated or frozen storage of a year or more. Opening a package and putting it into a glass jar with a tight fitting lid serves no useful purpose as the idea is to exclude as much oxygen from the package as possible, that's why the 454-gram bricks are vacuum packaged. By folding the packaging down around the IDY and securing tightly you effectively reduce the head space in the package and reduct the contact with the air in the package which is necessary for effectively storing the IDY.

[Re: Yeast - Fresh or IDY 112](#)

Condensation = water which will be absorbed into the dough over time, then when you go to bake the pizza there is a wet spot in the dough which produces copious amounts of steam or vapor pressure resulting in a beautiful bubble on your pizza.

[Re: Need help proofing my Sicilians 113](#)

In one of the later tests that we did on pizza we looked at what was the major cause of heart burn with individuals who ate pizza but had stopped eating it due to the heart burn issue. While it is true that highly acid foods can cause heart burn, in pizza we found that it was the dried basil and dried oregano that were more often than not the culprit. When we deleted these ingredients from the pizza and replaced them with fresh basil or oregano leaves our test group said that they did not experience the heart burn they had previously experienced and indicated that if given the opportunity to purchase the pizzas made using the fresh basil and/or oregano they would consume pizza more frequently. As an off-shoot from this study we also found that our sensory panel could taste the cheese better than when the dried counterparts were used. We confirmed these observations by making pizzas using only fresh basil and/or oregano and putting them out at the Ohio Pizza Show as well as the PMQ Pizza Show and asking samplers for their comments. The #1 comment was: "What kind of cheese was used to make this pizza? It has a great flavor!" We were using 4-ounces of Grande whole milk mozzarella on our 12-inch pizzas.

[Re: Which are the factors that affect digestibility? 114](#)

The crust that forms is actually insoluble so spraying with water really doesn't help much. Mixing it into the dough as you've done is OK and you'll probably not even

notice it with a thin crust pizza but in some cases it will form hard little bits (like what's this?) in the finished crust. The best way I've found to address this is to just leave the dough alone after covering it, then orient it so the crust is on the bottom when you open the dough into a skin. The way crackers are made is to sheet the dough into a continuous ribbon and apply heat along with airflow to the top of the dough to form a dry skin/crust. The dough is then laminated (referred to as dry laminating) and the process repeated again to achieve the desired flakiness in the finished cracker.

[Re: Left the lid off in the fridge - dry dough - what should I do?](#) **115**

You can certainly speed up the proofing process by placing the panned dough into an environment where you have not more than 105F with 85 to 87% relative humidity. A warm place with a damp towel draped over the pan seems to work pretty well for me (just be careful so the towel does not contact the dough or it will stick to it). I use a piece of plastic when proofing at room temperature but when proofing at an elevated temperature I get too much condensation formation on the plastic which drips onto the dough, the damp towel provides the humidity while preventing condensation from forming.

You will have to experiment with proofing times under YOUR conditions to arrive at a proofing time. Using four pans of panned dough, allow to proof for 15, 30, 45 and 60-minutes prior to baking, dress each pizza the same and bake all at the same temperature, then pick the one that you like best. If you have kept track of the times and temperatures and you can replicate the proofing conditions you will have your parameters for making your Sicilian style pizzas.

[Re: Need help proofing my Sicilians](#) **116**

When we did studies on IDY we found that 95F was the ideal water temperature for suspending the IDY in. A variation of as little as 5F higher or lower resulted in a reduction in gassing/fermentation performance with a greater loss in performance with a lower water temperature than 95F. This is not due to a difference in the yeast itself but instead in the way the yeast agglomerates are designed. They are designed to be fast/instant hydrating, as a result when hydrated in cold water glutathione is leached out of the cells which impairs the ability of the yeast to ferment and the now free glutathione will act as a reducing agent (just as "dead yeast"/RS-190) does making for a softer, more extensible dough condition at the expense of an inconsistent rate of fermentation.

[Re: Yeast - Fresh or IDY](#) **117**

Your issue is with fermentation, not proofing of the dough. Proofing is done after you fit the dough into the pan and it ends when you bake the pizza. Most Sicilian pizzas are proofed for about an hour before baking.

By all means reduce the yeast! Remember, we're making pizza dough, not nitroglycerin. Even in commercial application we have to make yeast and/or temperature adjustments for walk-in coolers which are very efficient and reach-in coolers which are not as efficient.

After you take the dough out of the fridge and open it up to fit the pan it will warm up quit fast but it's normal to pull the dough out of the fridge a couple hours before that to allow the dough to warm up (50 to 60F), so now the dough is actually at fermentation temperature already. I usually cover my Sicilian style pizzas with a sheet of plastic for the proofing stage. You will need to experiment with the proofing time depending upon your dough formula and dough management procedure to determine what time actually works best for you.

[Re: Need help proofing my Sicilians](#) **118**

When using IDY how are you adding it? The conversion from CY to IDY is to use roughly 60% less, not more. If you are machine mixing you can add the IDY directly into the flour providing the total mixing time is 5-minutes or more. The other way to add it is to suspend it in a small amount of 95F water (USE A THERMOMETER) and stir to suspend, there is no need to activate it as done with ADY.

The only real difference between CY and IDY is moisture content (approximately 80% for CY and 6% for IDY). Because IDY is instant hydrating (that's where its name comes from) it is very easily damaged if hydrated in water that is too hot or especially too cold.

[Re: Yeast - Fresh or IDY](#) **119**

The amount of diastatic malt, like all of the other ingredients, is based on the TOTAL flour weight which includes both the flour in the dough and the preferment.

[Re: Getting crust to brown without being to overcooked and hard](#) **120**

Pizzaman123;

That, my friend is how you can start another sourdough starter having like characteristics to the mother starter from which it was made.

[Re: Window Pane Test](#) **1381**

Made my day and got a good laugh from the thread. :-D :-D :-D

[Re: Decaf](#) **1382**

The easiest way to remove dough balls from a plastic tray is to use a specially designed dough scraper, designed just for removing the dough balls from the box with minimal distortion as well as scraping any residual dough out of the tray/box after its been emptied. The corners of the scraper are radiused the same as the inside box corners to make this an easy and effective task.

[Re: Dough sticking to plastic tray](#) **1383**

Huh? I always thought it was how one referenced a baby cow, "decow" and decaf were standing out in depasture" :-D

How to make decaffinated coffee taste better: put some type of flavoring into it.....like Baileys Irish Cream.

[Re: Decaf](#) **1384**

A sourdough starter and a biga are different animals. In the baking industry bigas are called liquid ferments or "brews" and are typically used at levels of 20 to 45% of the total flour weight with total fermentation time running from as short as one hour to as much as 5 or 6-hours. Sourdough starters are much more acid and also have a higher TTA (titratable acidity) which is why they are typically used at lower levels. They are allowed to ferment for days, not hours to develop their unique flavors and the type of fermentation is different too, in a biga the fermentation is yeast based while in a sourdough starter it is primarily bacterial based. For many years bakers have used "sours", not to be confused with sourdough starters, these sours are nothing more than old dough which has been allowed to ferment to develop acidity as well as flavor. It must be noted that the flavor obtained from these "sours" is nothing like that obtained from a sourdough starter.

[Re: Window Pane Test](#) **1385**

If your total dough weight is around 18-ounces or less there is essentially no difference between bulk and dough ball cold fermentation. This very topic was

discussed in significant detail not too terribly long ago.

Re: Bulk vs ball ferment**1386**

In order to be able to stretch the dough (window pane test) to see a clear gluten film at the mixer (immediately after mixing) the dough MUST be fully developed in the mixer, no two ways about it. You either develop the gluten matrix mechanically (mixing) or biochemically (fermentation). Bread doughs, by nature are essentially fully developed at the mixer but pizza doughs are only mixed to a point of just being incorporated or just to a point on being smooth, they are then subjected to rather lengthy fermentation times which allow for biochemical gluten development to take place, this is why if you stretch out a dough ball at the time of opening you will be able to see a much better formed gluten film than you did after mixing.

Re: Window Pane Test**1387**

My own personal preference is the KD-8000, I'm sure there are better scales available but for the money, capacity and accuracy the KD-8000 is awfully hard to beat. It also takes regular flashlight batteries that never seem to wear out. I use mine all the time for baking, making preserves and fruit butters, jerky and any other kitchen chore requiring me to weigh something. The only thing it might be lacking is the "finesse" in scaling accuracy to make very small doughs, but then I don't make those really small single pizza size doughs so it's not an issue for me, but if it was I could buy a second, smaller scale with the capacity and accuracy needed for those specific tasks. For those interested in my opinion on commercial application scales for use in a pizzeria the scales offered by AND Weighing <www.andweighing.com> / Stein Carlsen <scarlsen@andweighing.com> are really hard to beat. We used them at AIB for a good number of years and like a Timex watch, "they took a licking and kept on ticking", they're extremely durable, accurate and again, they use regular flashlight batteries.

Re: Scale recommendations.....**1388**

The longer you allow the dough balls to cold ferment the softer and more extensible (less elastic) they will become, additionally the longer the CF time the more flavorful the finished crust will become after baking. I suggest experimenting with different CF times to see what works best for you under YOUR specific conditions. I'm not sure what you mean by "letting it proof for a few hours"? The only proofing the dough receives is after the dough is fitted to a pan, such as when making a deep-dish pizza. When the dough balls are removed from the fridge after the CF period this is to allow the dough to warm sufficiently for ease of opening the ball into a skin, it is not a proofing period in the true sense. The difference between AP and bread flour is that AP flour has no specific application (that's what All Purpose means, while "bread" flour means that the wheat varieties that the flour is milled from are selected for their ability to make a strong dough (strong gluten) and have good fermentation tolerance which are all desirable characteristics for a bread type flour and are also desirable characteristics for a pizza flour too. In short, you have a better idea of what you are getting with a bread flour than with an all purpose flour. Some all purpose flours are quite good and work well for both bread and pizza while others do not. Bread type flours can generally be counted on to perform in a satisfactory manner across the board.

Re: HELP!!! Having trouble with 00 Tipo flour.**1389**

First off, put the "00" flour aside for now as it will not give you a dough that will brown properly (hardly at all) given the baking temperature you are using, instead, use a bread type flour that has been malted (it will indicate this on the bag). Rather

than working with a "recipe" in volumetric portions get a scale that will weigh in grams so you can weigh all of your ingredients, then get a thermometer to measure the dough temperature. I have a feeling that your water temperature might be WAY too warm. Fresh/compressed yeast isn't necessary you can use either active dry yeast (ADY or instant dry yeast (IDY) which form do you have available to you locally?

Here is a very good dough formula which I am showing in both bakers percent as well as grams.

Flour: 100% 600-grams

Salt: 2% 12-grams

IDY: 0.4% 2.4-grams OR ADY @ 0.5% 3-grams

Water: 390-grams/ml (75F/23.8C)

Procedure:

Put water in mixing bowl, then remove a small quantity (50-ml) and heat it up to 100F/37.7C (use the thermometer as this temperature is rather critical), put the yeast into the slightly warmed water along with a pinch of sugar and stir to suspend the yeast, set aside for 10-minutes to allow yeast to hydrate/activate, then pour into the water in the mixing bowl. Add the salt and immediately add the flour and begin mixing by hand or machine. If mixing by machine mix until a smooth dough is achieved, if mixing by hand just mix until ingredients are well incorporated, then cover the bowl with a piece of plastic and set aside to ferment for 90-minutes, turn the fermented dough out of the bowl (use a plastic scraper) onto a floured surface and knead the dough several minutes until it begins to look smooth, lightly oil the mixing bowl, form the kneaded dough into a ball and lightly oil it, then place it into the oiled mixing bowl, cover with the plastic and allow to ferment for 1 to 2-hours, turn the dough out of the bowl and knead for a minute or two, form into a ball, lightly oil and place back into the mixing bowl, lightly oil the top of the dough ball and place the bowl of dough into the fridge to cold ferment for 2-hours, then cover the bowl with the sheet of plastic and allow to continue cold fermenting for 18 to 48-hours. After the dough has cold fermented, remove it from the fridge and allow it to set at room temperature until the internal temperature of the dough ball reaches 60F/15.5C, it is then ready to remove from the bowl, place it onto a floured surface and open into a pizza skin by your preferred manner. Bake the pizza on a pre-heated pizza stone or steel as hot as possible (allow at least 1-hour to heat the stone or steel). If you want more color on the crust add 2% (12-grams) sugar to the dough formula.

This should give you a pretty decent pizza to begin working with.

[Re: HELP!!! Having trouble with 00 Tipo flour. 1390](#)

I don't know too much about it except that it is milled from soft wheat varieties as are other "00" type flours. The fermentation for this flour is limited to about 24-hours and it is not malted. It's just a guess, but I would think that Caputo "00" Pizzeria Flour would be a good substitute. Any U.S. milled flours are going to be made from hard wheat varieties so the dough is going to be somewhat different.

[Re: Polselli Super 1391](#)

I like it too, but my go to peel dust is a blend of equal parts of semolina flour, my regular pizza flour and fine grind corn meal. If you query 50 people as to what their favorite peel dust is you will get 50 different opinions. If it works for you and you're comfortable with it, use it. Many pizzerias use nothing but fine corn meal, some use rice flour and some use wheat bran or rice bran, just about anything goes.

[Re: Pizza hydration 1392](#)

When substituting ADY with IDY a good rule is to use 25% less IDY than the amount of ADY you're replacing. When it comes to high speed mixing and IDY even when using a VCM (1825 r.p.m. and about 70-seconds mixing time) the recommendation still stands to suspend the IDY in a small portion of 95 to 100F water. The reason for this is to endure that the yeast agglomerates (particles that you see in the bag) are thoroughly incorporated into the dough as opposed to be enveloped in the dough.

[Re: difference between IDY and ADY \(glutenboy method vs what Gemignani says\)](#) **1393**

Chicago Bob is spot on! When using a pan you will also be using a release agent such as oil or shortening in the pan which facilitates removing the finished pizza from the pan. Oil will give you a different crust characteristic than shortening. I like to say that oil will provide some level of a fried effect while shortening will provide a bread like crust. By increasing the amount of oil in the pan you can achieve a truly fried crust characteristic, oily like CB said, but fried and crispy. As for baking on a stone, I never liked the idea of baking pan pizzas on a stone as it can be difficult to control the bottom bake. When I bake pan pizzas in a deck oven I always place the pans on a pizza screen to give control over the bottom crust color. For something a little different you might try putting some cheese in the the outer crust (like P.H.) or how about putting some pepperoni in the crust rather than cheese?

[Re: Pan thick style vs with Stone](#) **1394**

That's a very good point with the excess bench/dusting flour. When the absorption reaches a point where, for whatever reason, excess dusting flour must be used to facilitate handling of the dough, and that flour cannot be removed before the pizza is taken to the oven any flour that is on the bottom of the skin can burn, resulting in a bitter taste. I've found this to be somewhat more problematic when the pizza is baked directly on the deck/stone than when it is baked on a screen, disk or pan. One might think of this as collateral damage from having a dough with an excessively high absorption.

[Re: Pizza hydration](#) **1395**

As with everything else, there are limits to the absorption used when making pizza crusts. To a point, increased absorption will promote greater porosity in the finished crust but only if the gluten strength is sufficient to carry the amount of water being added, and the oven is hot enough to provide the extra oven spring made possible by the higher absorption, additionally, the crust must set fast enough to lock-in the increased volume without without collapsing. All of this must be balanced against the amount of fermentation the dough is subjected to as fermentation has a mellowing/weakening effect upon the gluten structure of the dough which means even though a flour might be sufficiently strong to carry high a high dough absorption if it is subjected to excessive fermentation the gluten will be sufficiently degraded to render it incapable of carrying the high absorption and dough collapse or reduced oven spring will be the end result. Added on to all of this, there are certain genetic properties of the wheat from which the flour is made which will allow the protein/gluten structure to effectively carry more water than other wheat varieties. When breeding for new wheat varieties this is but one of the criteria assessed to determine if a variety will be released for future planting. Indeed, dough absorption can be a rather complex issue.

[Re: Pizza hydration](#) **1396**

I'm in the same boat, back when using a wood fired oven I was making doughs in the 70 to 75% range but now you will most often find me using something in the 62 to 65% range. The type of pizza that I most often make is a N.Y. or New Haven style using cold fermentation in the 2 to 4-day range. I like the flavor and textural properties of the finished crust when made this way, just my own personal preference.

[Re: Pizza hydration 1397](#)

A quick test to see if your dough is being over fermented for the specific flour being used is to reduce the total fermentation time by 1/3 (33.33%), if you see an improvement make further adjustments in the fermentation time. Also opening the dough in oil as opposed to flour might also be responsible so be sure to follow up on that too.

[Re: Causes of thin spots? 1398](#)

Welcome to the site!

I've visited Istanbul many times in the past, in fact it was my favorite city for holding regional meetings when I was on the McDonalds (hamburger chain) International Task Force. I used to stay at the Divon Hotel. Beautiful city with GREAT shopping.

[Re: Hello from Istanbul 1399](#)

The wood peels are not intended to be used in the oven, instead they are intended to be used as a prep-peel. In this application I think they are more forgiving than a metal peel as the wood will not contribute to the formation of condensation under the skin as a metal blade peel can if is allowed to ever get cold (this is a good reason for keeping your peels close to the oven). For many home pizza makers this can't always be done so care must be taken to prevent putting an opened skin on a cold metal peel. With a wood peel it really doesn't make too much difference if the peel is cold or not. I've also noticed that you can leave a dressed skin on a wood peel longer than on a metal peel before it begins to show a penchant for sticking. Its these two characteristics which make it more forgiving.

[Re: GI metal perforated versus solid turning peel 1400](#)

I would be inclined to go with the Deerfield unit. Good name and strong reputation in freezing equipment.

[Re: Blast Freezer question 1401](#)

Why not use bags? They are a lot easier to manage than trays and require a LOT less space too.

[Re: Help with dough process 1402](#)

The link took me to one that is only rated to -18C (-0.4F) which is not cold enough. You will need to have one that is rated to -37C or something close to it.

[Re: Blast Freezer question 1403](#)

Since you are going to be using the dough over a 4-hour period of time I think you might be ahead of the game by refrigerating the dough balls immediately after forming and then pulling the dough on a schedule which will allow the dough to warm over a 5 to 6-hour period of time before it is opened into skins for immediate use.

[Re: Help with dough process 1404](#)

That's a difficult question to answer as I have no idea of how strong your starter is or if it is a "natural" starter or one based on commercial yeast. The refrigeration process will slow the rate of fermentation regardless of the type of starter being used so I'm guessing that your best bet will be to refrigerate the dough balls and to give them at least 4-hours, or more, to regain activity before opening into skins once you're at the event.

Good Luck!

[Re: Need some help in a pinch](#)**1405**

You'll be making over 40 pizzas, over what period of time? What is your dough ball weight? How are you planning to bake the pizzas? In a typical home oven this could be an all day affair, if you have a commercial deck oven, depending upon the size of the oven and size of the pizzas it could take anything from 30-minutes to an hour or more.

[Re: Help with dough process](#)**1406**

Hopefully the dough felt slightly soft and slightly tacky too, if it didn't you might find that you are too low on absorption.

[Re: Whole wheat](#)**1407**

I've been to the store in Olathe, KS many times as it's near to where my son lives. The dough is yeast leavened, 50% absorption, and formed using a dough sheeter/roller. They use cutter pans (40-degree shoulder angle) and bake in deck ovens. To use the cutter pan just drape the sheeted skin over the pan and crimp cut by rolling a rolling pin over the top of the pan.

[Re: Pizza Shoppe-style?](#)**1408**

Kelly;

While you might "suck" at math, I'm betting that you can figure out the amount for a tip to leave after a meal out, right? If you can do that you can work with bakers percent.

Let's start with your dough "recipe" for a 12" pan. The first thing to do is to get a good scale that will weigh in grams. There are many very good ones available on the internet priced at or under \$50.00.

Portion each ingredient three times and weigh the portion each time and write it down. After you have done this for each ingredient add up the total weight for each ingredient and divide it by three, this will give you the average ingredient weight. Now divide the average weight for each ingredient by the total flour weight and multiply by 100. You have now put your dough "recipe" into a formula based on bakers percent. By the way, flour is ALWAYS 100%.

A 9-inch pan has a surface area of $3.14 \times (4.5^2)$ or $3.14 \times 20.25 = 63.585$ square inches.

A 12-inch pan has a surface area of $3.14 \times (6^2)$ or $3.14 \times 36 = 113.04$ square inches.

The difference in pan size is $113.04 - 63.585 = 49.455$ square inches.

Divide 49.455 by $113.04 \times 100 = 43.75\%$ difference in pan size. The 12-inch pan is 43.75% larger than the 9-inch pan. Or to put it another way, the 9-inch pan is 43.75% smaller than the 12-inch pan.

To find out how much flour to use in your dough formula for the 9-inch pan:

$100 - 43.75 = 56.25\%$ Your new dough formula will use only 56.25% of the flour weight needed to make the dough for a 12-inch pan.

This is where being able to calculate the amount of a tip comes in handy:

To find your new flour weight for the 9-inch pan, using the flour weight for the 12-inch pan multiply the weight by 56.25 and press the percent key and read the new flour weight in the display.

To find the weight for each of the other ingredients enter the new flour weight for the 9-inch pan then press "X" and enter the bakers percent for that ingredient and press the "%" key, read the ingredient weight in the display.

In this case the flour weight is the cost of the meal and the percent of each ingredient is the amount of tip you want to leave.

You can also use an Excel Spread Sheet to find the ingredient amounts too but you first need to convert your dough "recipe" into a formula based on bakers percent.

[**Re: Math & Pizza**](#)**1409**

Additionally, you didn't provide any information on how you activated the ADY.

[**Re: Dough Not Rising - Help!**](#)**1410**

Yup, you've identified the culprit. When using a plastic fat, like Crisco, the dough acts as if it were glued to the pan with contact cement. The fat holds the dough to the pan sufficiently long for it to fully relax and not pull away from the edges. When using oil the only really effective action is to press the dough out in the pan several times with at least a 30-minute rest period between each session of fitting the dough to the pan. You can also use your Crisco on the sides of the pan and olive oil on the center portion of the pan if you want to go that route. In my experience even a fully relaxed dough will tend to pull away from the sides of the pan when using only oil in the pan unless you press fit it into the pan multiple times.

[**Re: Pressing dough to edge of pan**](#)**1411**

Proofed, frozen and straight to the oven = Freschetta brand frozen pizzas.

I am not aware of anything along the lines of what you are looking for, nothing that small.

To make pre-proofed frozen pizza you will need to have a freezer capable of reaching temperatures in the -25 to -38F range (ammonia refrigerant) or it will need to be a cryogenic freezer using an industrial cryogen (liquid carbon dioxide or liquid nitrogen) usually adjusted to freeze at -45 to -60F.

[**Re: Blast Freezer question**](#)**1412**

Thank you Peter, I don't know what we'd do without you!

[**Re: Whole wheat**](#)**1413**

When you re-ball an over fermented dough the gluten tightens up to the point of being non-elastic (don't need to tell you that) :-D.

You will then need to allow time for the gluten structure to relax once again, depending upon how much over fermented the dough is, this could take anything from 2 or 3-hours to as much as 5 or 6-hours.

Why did the dough blow?

What was the finished dough temperature?

Was the correct amount of yeast used?

Did you leave the dough box open (cross-stacked) for a few hours when you placed it into the fridge?

Did you leave at least 2-inches of space between the dough balls in the box?

Did the amount of dough placed into your fridge cause the temperature to rise in the fridge?

Remember, when loading several dough balls into a home fridge it may be advantageous to lower the finished dough temperature to the 65 to 70F range to

compensate for the home fridge.

[**Re: Rescuing balled CF dough**](#)**1414**

Actually, whole-wheat flour really doesn't make an unusually dense loaf of bread IF YOU USE THE CORRECT DOUGH ABSORPTION. If you do a search in the archives you will find discussion on how to find the absorption of YOUR SPECIFIC whole-wheat flour. I've also written an article on it too. Getting the absorption correct is the key in making decent dough and finished products using any kind of whole-wheat flour, you will also need to make a "soaker" from the whole-wheat flour aka autolyse. Forty five to sixty minutes is about right for the hydration time as the bran takes some time to hydrate.

[**Re: Whole wheat**](#)**1415**

Even low temperature pasteurization requires heating to 180F and maintaining that temperature for 30-minutes.

I'll take a pass on anything canned at 140F.

[**Re: Cooked Sauce yuk!**](#)**1416**

Matt;

Fermentation is more than carbon dioxide production, it is also production of acids and the effects of various enzymes on the gluten forming proteins of the flour. Refrigeration of the dough limits the production of acids and the work of the enzymes resulting in under fermented dough characteristics and performance properties. There is a point in dough rheology where both under fermented dough and over fermented dough have identical characteristics and the only real way to sort them out is by TTA (titratable acidity) of dough itself with a greater TTA being present in the over fermented dough.

[**Re: Causes of thin spots?**](#)**1417**

That's a "new" one to me.

[**Re: Cooked Sauce yuk!**](#)**1418**

The only thing I would add is after baking with your new starter, if you like the results, use a portion of it to start another one (use different tools and containers) as a back-up reserve. Starters are easily lost through contamination regular bakers yeast is a contaminant in this case and it can be all but impossible to replicate your original starter. This is why we always say if you don't like your new starter, sanitize your tools, possibly change locations where it's made, and try another one, but just like your computer data, it's always a good idea to back it up. I store my back-up in the fridge and only feed it weekly and it does quite well.

Note:

When I was at AIB my first starters were total failures in my opinion, we had sooo many yeast cells floating around in the air that the yeast always became the dominant micro flora and the resulting flavor was always like that of yeast leavened dough. It wasn't until we took it out of that environment that we were able to make a decent sourdough starter.

[**Re: what sort of flour to use to make my own starter?**](#)**1419**

To be considered whole-wheat all of the flour used in making the crust has to be whole-wheat (no white flour allowed). However, if you want to make a wheat crust I would recommend using a blend of 70% white flour and 30% whole-wheat flour.

[**Re: Whole wheat**](#)**1420**

Matt;

Typical causes are:

Insufficient dough fermentation.
Excessive dough fermentation.
Insufficient dough absorption.
Opening technique.
Insufficient dough weight.

From the looks of the opened skin I'm guessing insufficient dough fermentation is the problem here.

If you want to see if it's technique use a rolling pin and carefully open the dough to within 2-inches of the full diameter, then complete the opening of the dough skin by hand.

[Re: Causes of thin spots? 1421](#)

Keep us posted on your progress.

[Re: Troubleshooting my Last Bake 1422](#)

Commercially manufactured sauce as well as tomato products are indeed cooked, they are heated under very controlled conditions to render them safe for the canning process and then quickly cooled to prevent further loss of volatiles which detract from the flavor profile of the product.

[Re: Cooked Sauce yuk! 1423](#)

How do you measure the oven and baking steel temperature, do you use an IR thermometer?

[Re: Troubleshooting my Last Bake 1424](#)

In looking at the color of your last pizzas, what is the protein content of your flour and please confirm if it's malted or un-malted. How does the bottom of the pizza look? Decent color or light? I'm guessing that the problem might be a bake issue so also please provide baking information such as temperature, baking platform (what are you baking your pizzas on?) as well as rack position in the oven.

[Re: Troubleshooting my Last Bake 1425](#)

Oops! Sorry about that!

Good catch there, you're right, it should equal 75%. So the corrected absorption should be $107.8 + 75.95 = 183.75$ which is 75% of 245 (total flour weight). The dough side water amount should show as 75.95-grams while the absorption next to it should be shown as 75%.

[Re: Martin's Potato Roll - Is it worth the HYPE? 1426](#)

Your calculations are indeed correct.

[Re: Best recipe for thin crust dough? 1427](#)

Allow me to correct it for you.

It looks like you are using 245-grams of total flour weight.

SPONGE:

Flour: 196 g (80%)

Water: 107.8 g

IDY: 3.675 g

DOUGH:

Flour: 49 g

Water: 26.95 g ($107.8 + 26.95 = 55\%$ of 245)

IDY: 1.225 g

The remainder of the math looks to be OK.

Milk: A high priced form of water. Contains lactose sugar which contributes to crust color development, the formula already has 13% sugar plus dehydrated potatoes for PLENTY of crust color development. The flavor improvement from milk comes from the butterfat content the formula already contains BUTTER. The calcium content of the milk might improve the handling properties of the dough but you can get the same improvement using calcium sulfate at 0.25 to 0.5%. Calcium sulfate aka GYPSUM is readily available from many sources including pharmacies.

[Re: Martin's Potato Roll - Is it worth the HYPE? 1428](#)

The easiest way to find the "desired water temperature" is to subtract the flour temperature from "145". As for mixing time, whatever time it takes to achieve a smooth, appearing dough, this is usually around 8 to 11-minutes, I've never seen it in the 3 to 4-minute range in a planetary mixer. The amount of ADY specified is indeed correct.

[Re: Best recipe for thin crust dough? 1429](#)

How big is your "bulk" dough?

[Re: Bulk CF and balling 1430](#)

Flour: 100% (12 top 12.8% protein content)

Salt: 2%

ADY: 0.5%

Oil: 1%

Too bad you don't use any water, but if you did I would expect it to be in the 52 to 55% range.

Mixing: That 20-quart mixer is a poor choice for this type of dough as it isn't powerful enough and there is a distinct probability of destroying the composite sacrificial gears in the mixer. A larger planetary mixer or a small spiral mixer would be a much better choice. Remember, no mixer, no dough.

Put water and yeast suspension in the bowl first, then add the flour and salt, mix 2-minutes at low speed, add the oil and continue mixing at low or medium speed (3rd. speed is for mixing cake batters only) until a smooth dough is achieved.

Target finished dough temperature is 75 to 80F.

Take dough to bench immediately after mixing and scale 10.5 to 11-ounces for 12" pizzas.

Form dough into balls, place into dough trays, wipe the top of each dough ball with oil, cross-stack in the cooler until the internal dough ball temperature reaches 50F (about 2-hours +/-), then down-stack or cover the dough boxes and allow to cold ferment for a minimum of 24-hours (36 to 48-hours is better). Remove dough box from cooler, allow to warm AT (AT) room temperature until the internal dough ball temperature reaches 50F then begin opening into skins for immediate use. Once you begin opening the dough balls into skins the remainder will remain good to use for about 3-hours.

Optional: After opening the skin use a docking wheel to dock the skins prior to dressing.

[Re: Best recipe for thin crust dough? 1431](#)

With less than 4-minutes mixing time there is a distinct probability that the yeast is

still present in the dough in the form of agglomerates (clumps) rather than dispersed as single cells. This means that you will experience inconsistent yeast activity/fermentation and some of the yeast cells will die and release glutathione into the dough making it soft and sticky/tacky. So in your case it is highly suggested that you suspend the IDY in warm (95F) water prior to adding it to the dough. From your description it sounds like a HOT dough rather than a "warm" dough. Remember, you will begin to damage the yeast at temperatures approaching 120F and thermal death point is at about 140F. In any case, I think you need to be looking at using cold or ice water for the bulk of the dough water to get the finished dough temperature into the desired temperature range of 75 to 80F.

[Re: Troubleshooting my Last Bake](#)**1432**

I second the motion. ^^^

[Re: Barley Malt](#)**1433**

Allowing the dough balls to come up to room temperature is allowing them to warm up too much, you only want to allow them to warm AT (AT) room temperature until they reach an internal temperature of 55 to 60F. In a commercial/pizzeria we use 50F which allows the dough balls to have a 2.5 to 3-hour use period after they reach 50F. It's normal for the dough to stick to the box, this is why they make special hard plastic scrapers for removing the dough balls from the box with minimum distortion. You can also use a flexible bowl scraper pretty well to the same effect.

[Re: Dough sticks to box](#)**1434**

Here is a good starting point for your potato buns;

Flour: 100% (strong bread type flour with about 12% protein content)

Salt: 2%

Dehydrated potato flakes (non-sulfited): 8%

Sugar: 13%

Shortening: 4%

Instant dry yeast: 2%

Water: 75% (variable)

The buns are best made using an 80/20 sponge-dough process with 1.5% of the IDY in the sponge and the remaining 0.5% added to the dough side as a yeast spike. Sponge absorption should be 55%. The dehydrated potato flakes are added at the dough side. The dough should be mixed to full gluten development. The dough then goes directly from mixing to forming with about a 60-minute final proof before baking at 420F/215.5C for about 15-minutes.

[Re: Martin's Potato Roll - Is it worth the HYPE?](#)**1435**

Proofer;

What part of San Diego are you in? My wife is from La Mesa, (she was a school teacher at Chesterton Elementary School) not too far from the country club.

[Re: "Achieve a Lighter, Tastier Thick Crust Pizza" .. Formulation Change from Tom L.](#)**1436**

Going back to the previously asked question, what was the finished dough temperature (temperature of the dough immediately after mixing)? This is a very important temperature as it will determine how the dough ferments. Also, what is the total mixing time in the processor? If the total mixing time is less than

4-minutes it is highly recommended that the IDY be suspended in a small amount of warm (95F/32.2C) water prior to addition to the dough.

[Re: Troubleshooting my Last Bake](#)**1437**

Additionally, don't forget to lightly oil the dough balls as you place them into the containers and leave the lids off for at least 2-hours or until the internal dough ball temperature reaches 50F, then apply the lids. This will keep condensation from forming inside the containers making for a wet, sticky dough with a penchant for bubbling during baking.

If you research this in the archives this is what we refer to as cross-stacking and down-stacking.

[Re: Troubleshooting my Last Bake](#)**1438**

Mouly;

You mention problems with transferring the prepared skin from the table onto the peel. You might think about getting a short handle wood prep peel. The opened skin is placed on the peel with a little dusting flour under the skin, the skin is then dressed right on the peel and peeled into the oven.

[Re: What can cause dough to be too stretchy?](#)**1439**

Sure, do it all the time.

Here is the basic procedure:

- 1) Mix
- 2) Scale and ball
- 3) Cold ferment for 24-hours
- 4) Remove dough from cooler and allow to temper AT room temperature for 60-minutes.
- 5) Open dough balls and place into prepared pans.
- 6) Allow panned dough to rest at room temperature for 45-minutes.
- 7) Re-stretch dough to fit pan as it will shrink back during the 45-minute rest period.
- 8) Allow the dough to rest for 30-minutes, and re-stretch again if necessary and place in the cooler. Cover with a sheet of plastic to prevent drying.
- 9) The panned dough should be ready to use after about 2-hours in the cooler and it will keep for the entire day.

Note:

All dough formulas are different so you will need to experiment with the time in step #8 to determine the correct time that will allow the dough to rise to the desired height during baking.

The dough can be taken directly from the cooler to the prep station and then directly to the oven for baking.

[Re: Detroit Style - New Way of doing things](#)**1440**

Allowing the dough to rest (begin to ferment) for 20-minutes before scaling and balling and CF reduces the ability of the dough to be cooled at a consistent rate so it is actually introducing variability into the process. Finished dough temperature becomes MUCH more critical and that 20-minute rest period has to have a very hard line, not 25 or 30-minutes (we all know human nature). On the other hand it can give you the fermentation effects of a longer time with a shorter fermentation time and maybe more importantly, it can improve the handling properties of the dough during the scaling and balling process, this is important with some high absorption doughs which tend to be somewhat sticky immediately after mixing. To someone making pizzas at home I really don't think it means a lot as to which way

you do it (with or without a 20-minute rest period prior to scaling and balling) as you are not trying to make 200 pizzas all look alike and you are not dealing with "hired help" to make the pizzas so staying on schedule is not that much of an issue and if it is you know exactly who to blame ;D

[**Re: My First Post - American Style Dough**](#)**1441**

To answer your questions, by "rest" you mean fermentation, the answer is yes because this is where the biochemical gluten development takes place. More mixing time/mixing at a higher speed will also develop the gluten, this is basically the way its done in modern high speed bread bakeries where gluten development is a critical factor. Temperature also plays a role as it controls the rate of fermentation. Colder doughs or colder fermentation environments retard the fermentation process so a longer fermentation time is required for the biochemical gluten development to take place.

I think you're over thinking this, just about any properly managed dough will have full gluten development at the time the dough is being opened into a skin. We have discussed machine mixing v/s biochemical gluten development a number of time here, a search through the archives should provide you with some additional reading material.

[**Re: The elasticity and gas problems strike a somewhat experienced pizzaiolo...**](#)**1442**

What you are referencing is referred to as "webbing" of the gluten film, it is an indication of under development. Pizza doughs are always under mixed so don't look for a clear gluten film after mixing unless you're making bread. If you have managed your dough properly you will be able to see a clear gluten film in your dough balls when you open them into skins. When we held our annual pizza seminars we used to open a 12-ounce dough ball to nearly 30-inches in diameter with 4 to 5 people standing in a circle opening the dough together, you could clearly see your skin details through the dough membrane when it was opened about as far as we could get it to go without tearing.

[**Re: The elasticity and gas problems strike a somewhat experienced pizzaiolo...**](#)**1443**

Wipe the top of each dough ball with a little oil before placing the box in the fridge. This will prevent the dry skin from forming. We have discussed this method numerous times if you want to search the archives for some extra curricular reading. When cross-stacking the idea is to allow the dough boxes to remain cross-stacked until the internal dough ball temperature reaches 50F, then the boxes can be down-stacked or lidded.

[**Re: The elasticity and gas problems strike a somewhat experienced pizzaiolo...**](#)**1444**

Don't worry about over kneading the dough by hand, it is all but impossible to do so. As for gluten development, biochemical gluten development will do that for you given that the dough will be allowed to ferment for at least 6-hours after mixing. You say your crust does not get crispy, what kind of color are you getting on the top and bottom of the crust? In some convection ovens you get too much top color and not enough bottom color which indicates a poor bake which can result in a less than crispy crust. Also not using sufficient dough for the pizza size can result in loss of crispiness (I personally use a dough loading factor of 0.088 to 0.097 for my 12-inch pizzas). In addition to experimenting with the rack position you might also experiment with turning the convection feature on your oven off as this can result

in a more balanced top and bottom bake.

[Re: My First Post - American Style Dough](#)**1445**

Two things might be at play here. First, the salt level is VERY LOW at only 0.2%, I suggest increasing it to something in the 1.75 to 2.5% range, and second I see you are using dough boxes, are you cross-stacking them for at least two hours before lidding them? If you are not cross-stacking them the dough is both over fermenting as it cannot cool down at a consistent rate and it is also sweating in the box (both of which result in the dough balls flowing together into a single mass).

[Re: The elasticity and gas problems strike a somewhat experienced pizzaiolo...](#)**1446**

Doing the easy things first, I'd suggest increasing the dough absorption in 2% increments to 62 and 64% to see if that helps. High baking temps demand a high absorption dough that expands readily. Also, when opening your skins be sure to keep your fingers away from the edge.

In the mean time if you can share exactly what you are doing aka dough management (be sure to include times and temperatures) it will help us to better determine what the issue might be.

[Re: Why the edge isn't puffed ? \(photo\)](#)**1447**

While all of the things you've mentioned will most certainly contribute to a soft, limp crust I believe that the number one, and most common cause results from improper baking. Baking the pizza at too high of a temperature or short baking (not baking long enough) the pizza are common causes. Additionally, dough that is too dense or opened into a skin that is too thin are also likely causes. A dense dough often results when the dough is opened into a skin by manually pinning the dough to shape it. A skin that is too thin results when one doesn't have sufficient dough ball weight for the size of pizza being made or they erroneously believe that by making the dough thinner it will bake out crispier. The last of the common things that I've found results from allowing the dressed or sauced pizzas to set for a period of time before baking. In this case the moisture from the sauce and/or toppings will migrate into the dough where it will be impossible to bake out resulting in a limp crust AND the development of the "dreaded gum line" just under the sauce. Aside from all of this, remember, just placing the hot pizza on a metal pan or cold surface will result in condensation forming at the interface of the crust creating a wet, soggy pizza. I could probably write a book on this topic alone but these are the most commonly encountered reasons for a limp crust when making pizzas at home, a whole new chapter is started when we discuss this problem at the pizzeria level.

[Re: The science of sloppy dough](#)**1448**

The sweetness and impact on crust color from honey and sucrose are the same. Honey is a mix of dextrose and fructose while the enzyme invertase in the yeast (and other microorganisms) hydrolyzes the disaccharide sucrose into its component sugars dextrose and fructose, so in the dough both end up being the same. This is one reason why it can be difficult to ascertain if sugar (sucrose) or honey was used as an ingredient in a yeast leavened baked product. With regard to flavor from honey, aside from sweetness, you would need to get to around the 5% level to detect and flavor from the honey, also keep in mind that the darker the color of the honey the more robust the flavor is, it's also cheaper too. Commercial grade aka bakery grade honey is about the color of black coffee so some care has to be taken or the color of the honey can impact the crumb color making it a dirty gray color,

not too bad in a pizza crust but it can be a real problem in bread items where a greater crumb portion is present and more readily visible to the consumer.

[Re: Caputo Confusion](#) **1449**

No difference in taste, just convenience and one less thing to go wrong, go wrong, go wrong, go wrong.

[Re: gooey dough](#) **1450**

I've worked with a number of mobile pizza operations over the years and from what I've seen is that yeast performs better than a sourdough starter under these conditions. This is because the yeast leavened doughs tolerate the cold temperatures better than the culture you have growing in your starter which likes to be kept warm and as you know is counter productive to keeping the dough for any period of time as it tends to get away from you as you have already indicated. Your best bet might be to freeze the dough balls a day ahead of time and set them out to thaw on the day of the event. Thawing time should be relatively short owing to the smaller size dough balls you will most likely be working with (TIP: flatten the balls into "pucks" when you freeze them as they will slack-out faster in this form). You could have one stack of dough trays covered in an insulating wrap (this will be your main supply) and another stack of dough boxes without the insulating wrap which will allow them to slack-out in a few hours and be ready for use. Since all doughs are different you will need to experiment to determine how long these slacked-out dough balls will remain good to use, I'm guessing several hours.

[Re: Dough Management for Mobile Units](#) **1451**

BJ;

I forgot to show the oil in my dough formula. I normally include 2% oil in the dough. When adding the oil use the delayed oil addition mixing method, by this method you hold out the oil for the first 2-minutes of mixing, then add it, mix 1-minute at low speed then continue mixing at medium speed until you get the targeted smooth dough consistency.

[Re: gooey dough](#) **1452**

If adding a liquid fat such as oils and melted solid fats in most cases they should be added using the delayed oil mixing method to prevent them from being absorbed into the flour. When adding a solid or plastic fat such as butter, margarine or lard they are best added right along with the flour.

How to determine if the delayed oil addition method needs to be used? Place a small quantity of the fat in question in a small bowl, sprinkle with flour, if the flour absorbs the fat the delayed fat addition method should be used, if it isn't absorbed into the flour the fat can be added along with the flour.

NOTE: Solid/plastic fats should always be added at room temperature or slightly softened. The only exception to this is when we are making a dough where we want to have pieces of the fat dispersed throughout the dough, in that case the fat is frozen and shaved/chipped, and added as a frozen fat so it does not become incorporated into the dough but instead remains as individual fat pieces. This is how a pie crust and many biscuit doughs are made.

[Re: "Achieve a Lighter, Tastier Thick Crust Pizza".. Formulation Change from Tom L.](#) **1453**

Your first step is the convert your dough (recipe?) into a dough "formula" based on bakers percent. To do this you will need to have the weight of each ingredient including the weight of the starter added to the dough. Then divide the weight of

each ingredient as well as the starter by the weight of the flour and multiply by 100. This will give you the ingredient weight in bakers percent.

Once you have your dough formula in bakers percent you can manipulate the size of the dough as desired.

To find the ingredient weight for a new flour weight, using your calculator, enter the new flour weight, then press "X" and enter the bakers percent of the ingredient you want the weight for, now press the "%" key and read the weight of the ingredient in the display. Repeat this for each ingredient including the starter and you will have all of the correct ingredient weights for the new flour weight.

[Re: Bulk Dough Making](#) **1454**

In my humble opinion, a New Haven pizza is just a crispy version of a New York style pizza so any New York pizza dough formula should work well for you.

[Re: new haven dough recipe](#) **1455**

I think the ingredient missing from your dough formula is sugar. If you add sugar you can manipulate, to some extent, the rate and way the crust bakes. I'd go back to your best effort at 100% bottom airflow and add 1% sugar to the dough formula. This will result in the crust browning faster and absorbing heat better for a more thorough bake in the short baking time being employed. If 1% sugar isn't sufficient go to 2% sugar, from there make incremental 0.5% adjustments in the amount of sugar.

NOTE: Due to the extremely efficient heat transfer properties of an air impingement oven the response to sugar in this type of oven is rather fast and at times dramatic so once you find a sugar level that works for you you will need to be "spot-on" with removing the pizzas from the oven, not a problem with a conveyor model but this can be problematic with air deck ovens which is one of the main reasons why I don't encourage fast bakes with this type of oven.

[Re: Dough Experiments - Guidance](#) **1456**

For ADY use 1/3 more than you would if using IDY.

[Re: Suggestion for oven temp](#) **1457**

Forgot to add, try making your pizzas using different types of fats, such as pomace grade olive oil, bacon fat (really good), butter (both fresh and aged for about 3-weeks by letting it set on the kitchen table).

[Re: "Achieve a Lighter, Tastier Thick Crust Pizza".. Formulation Change from Tom L.](#) **1458**

Your pizza looks pretty AWESOME!

[Re: "Achieve a Lighter, Tastier Thick Crust Pizza".. Formulation Change from Tom L.](#) **1459**

Are you looking to use this for your cold fermentation space or are you planning to use it just for temporary holding of the dough for use during the day? The reason why I ask is because I've used prep-table storage at many pizza shows and I can attest to the fact that it just isn't up to holding any quantity of dough under sufficiently cold conditions to work if you are going to CF the dough for much more than about 18-hours. The units were never designed for that purpose. While not the best choice, a much better option for holding the dough during the CF period in a small shop would be a reach-in cooler or a rack type cooler. Reach-in coolers will not allow you to cross-stack the dough boxes so you will need to off-set them front to back for the cross-stack period.

[Re: Need help with dough storage!!!!](#)**1460**

Big Dave used to have his "Old Faithful", here's mine;
Flour: 12 to 12.8% protein content 100%
Salt: 1.75%
Sugar: (optional) 2%
IDY: 0.375%
Water: (variable) 64%

Mix just to a smooth consistency.

Targeted finished dough temperature: 75 to 80F.

Immediately scale and ball.

Place in fermentation container(s).

Wipe the top of each dough ball with a little oil.

Place in fridge UNCOVERED for 2-hours.

Cover container(s).

CF for 24 to 48-hours. 48-hours is better than 24-hours.

Remove from fridge and allow to TEMPER AT room temperature for 2-hours or until the center/core temperature of a dough ball reaches 60F before starting to open into skins.

The window of time to use the dough balls is about 2-hours from the time they reach a core temperature of 60F.

[Re: gooey dough](#)**1461**

I've had my best success with NY style pizzas using a baking temperature of 500 to 550F. If you don't mind your pizzas being a little softer and chewier bake at 700F.

[Re: Suggestion for oven temp](#)**1462**

BJ;

Try increasing the yeast a little, now that you are controlling the rate of fermentation your dough might need a little more yeast to meet your specific needs or you might try increasing the finished dough temperature by 2 to 3F. I'd try the increased dough temperature first (increase the temperature of the dough water by 5F) and if that doesn't work go with the increased yeast.

[Re: gooey dough](#)**1463**

Regarding your peel issues, get your fermentation dialed in correctly and then, if you still have problems peeling the pizza into the oven begin incrementally reducing the dough absorption to tighten the dough up a little. Remember, every dough has a "sweet spot" when it comes to absorption, you can't just take an absorption percent and plug it into your dough and expect it to always work. This is due to lot to lot variations in flour absorption (we recently discussed this there) as well as differences in the specific way the dough is being managed as well as ones ability to handle a soft dough.

[Re: What can cause dough to be too stretchy?](#)**1464**

Here's a tip to keep condensation from forming in the fermentation container.

Lightly oil the dough ball as you place it into the fermentation container, then place into the fridge but DO NOT cover it for at least two hours, then apply the lid and condensation will not be a problem. Warm dough going into a cold fridge will ALWAYS form condensation on the top of the container, by leaving it uncovered (cross-stacked) for at least two hours the dough will have sufficiently chilled so condensation will not be much, if any, issue after covering. This same condensation

will make the dough sticky and it might be what's causing the dough to stick to the container too.

[Re: CF dough sticking?](#) **1465**

Gluten is what makes the finished crust tough/chewy and fermentation degrades the gluten (sufficient fermentation will turn a dough into soup as it destroys the protein/gluten) so a longer fermentation time will naturally give rise to a more tender eating crust. Actually, 24-hours is a pretty short fermentation time even with the short bulk fermentation time (which is really just fermenting the dough in ball form unless your total dough weight is more than about 18-ounces). My suggestion is to keep the IDY at the same 0.3% level, adjust the water temperature to give you a finished dough temperature in the 75 to 80F range ball immediately after mixing and CF for at least 48-hours. Bench mark from there to find the fermentation time that works best for you.

[Re: Struggling with tough crusts](#) **1466**

The type of fat used won't impact the way the dough handles to any great extent, I say this because oil, being a liquid, will help to make the dough a tad softer however it does not impact the extensibility characteristics of the dough. Plastic type fats are most commonly used in thick crust and pan-style pizzas where they help volume of the crust by providing additional strength to the dough during final proofing which in turn improves oven spring characteristics of the dough.

[Re: "Achieve a Lighter, Tastier Thick Crust Pizza" .. Formulation Change from Tom L.](#) **1467**

Proofer:

You will need to use 0.6% IDY to replicate the performance of 1.5% CY. I'm not sure what you mean when you ask about different volumes when referencing fats? Assuming you are weighing your ingredients an ounce of oil is the same as an ounce of butter or lard just as an ounce of ice is the same as an ounce of water.

[Re: "Achieve a Lighter, Tastier Thick Crust Pizza" .. Formulation Change from Tom L.](#) **1468**

I use a simple pastry brush with soft bristles. In this case less oil is more desirable, all you want is an oil shine on the skin. Spraying puts WWAAYY too much oil on the skin.

Tip: A good artificial bristle paint brush 1.5 to 2-inches wide works great.

[Re: Sauce bleed -through](#) **1469**

My preference is to add the water, then suspend the CY in the water, add the flour and salt together and mix just until a smooth dough is achieved. This results in a more uniform dough than is achieved if the flour is added in stages.

If you are using a dough absorption over 70% you may find it advantageous to put the water in the bowl followed by the flour and mix just enough to incorporate the flour, then allow this (autolyse) to rest for about 30-minutes, add the CY and mix for 2-minutes then add the salt and mix until a smooth dough is achieved.

[Re: adding flour during mix](#) **1470**

I've never heard of pure lecithin being an egg "replacement". One whole egg only contains about 125 milligrams of lecithin with the remainder being mostly water, protein and fat. While the lecithin could be a stand-in for the fat content it certainly won't coagulate like the egg protein does and it will contribute little to no impact upon the browning reaction due to the protein content and this doesn't even

address the nutritional properties of the egg.

[Re: Bakingbusiness.com Article: Emulsifiers](#)**1471**

I was in Sydney, Australia a number of years ago when we had a monsoon come shore, it dumped the equivalent of 42-inches of rain in 24-hours, it was like having a fire hose pointed directly at you for 24-hours! Not exactly something I would want to go through again if I could help it.

To all of our friends in the path of the storm I echo the words of Jackitup; Stay safe!

[Re: Houston Floods.....AGAIN!!!](#)**1472**

It all depends upon how big your "bulk" dough is weight wise, will assume it's in a bowl. There are also lots of other factors which could influence how the dough preforms under such conditions too, such as the finished dough temperature and if the dough is covered or left open for a period of time (cross-stacked) after being placed in the fridge. The short answer to your question is that if your total dough weight is about 18-ounces or less your "bulk" dough is really just a larger size dough ball and it will act as one during the cold fermentation period.

[Re: Bulk Ferment in Fridge for 48 hours??](#)**1473**

Yes, but please define "portable" for your specific needs.

[Re: Deck ovens](#)**1474**

The attachments as well as the attachment method appear to be very much like that of a Hobart mixer. You might want to see if Hobart mixing attachments will fit it.

[Re: Second-hand Mixer Score](#)**1475**

While Teflon works with releasing baked dough (crust) it will not release raw dough as is the case when peeling a pizza into the oven. Sticking is not an issue with an oven peel since the dough is already baked and crusted. The idea with a prep peel is to put a coarse material onto the peel as a "peel dust" before placing the dough skin onto the peel, the peel dust will act as ball bearings under the dough to allow it to be easily shuffled off of the peel either in a single stroke or several short strokes.

[Re: Non-stick Peel](#)**1476**

Also, as I've said so many times before, oil/fat is a "tenderizer" as such it contributes greatly to a more tender eating characteristic of the finished pizza. If you want to see this first hand just buy two packages of tortillas, one a regular tortilla and the other a fat free tortilla, eat one of each and you will see how it influences the texture of the tortilla. It does the same thing in pizza crusts too.

[Re: Struggling with tough crusts](#)**1477**

Absolutely! There really isn't anything very special about the PH thick crust dough that would prohibit its use in making a thin crust pizza. There are some commercial frozen pizzas being made using cold pressing equipment which requires the skin to be pressed onto a special pan, and since a pan comes into play oil is needed to facilitate release of the crust from the pan (crusts are par-baked) hence they are fried as opposed to being baked in the traditional manner and don't forget about the Celeste brand frozen pizzas, they are made using a fried crust. Frying absolutely improves the crispiness of the finished crust (any crust formulation), so if you want to use a PH thick crust clone dough formulation and bake it in a pan using oil as a thin crust go for it, it will absolutely work.

[Re: PH pan rolled thin?](#)**1478**

I did quite a bit of work with the different Caputo flours last year, the Caputo Pizzeria, while high in protein content doesn't exhibit good fermentation tolerance which is a characteristic of the soft wheat protein as opposed to the amount of protein present. When it comes to adding sourdough starters it's a wild guess as to how much to use unless you know both the pH and TTA of the starter you're adding. It might be a case of your starter just being too strong at the 20% level so my first inclination would be to use it at a lower use level, maybe try it at 15% and then 10% to see if that helps any. Remember, a dough that has excessive acidity will be weak and tear easily and it also might show signs of being difficult to achieve a decent bottom crust color.

[Re: A Couple of Dough Management Questions](#)**1479**

First off, 0.2 to 0.3% IDY is not exactly what I'd call a "trace" amount of IDY, it's essentially a full dose of IDY for a CF dough. This in itself might be the source of some of your issues? I wouldn't recommend going to the lower finished dough temperature as you've proposed since it will be much more difficult to consistently achieve (the further your targeted finished dough temperature is from the room temperature the more difficult it will be to consistently achieve your targeted finished dough temperature. My advice is to keep it where its at in the 70 to 75F range.

Tom Lehmann/ The Dough Doctor

[Re: stretch and fold and FDT](#)**1480**

It's impossible to comment on your question regarding the yeast amount as we don't know how much you're presently using, but the advice you got about using a fork type mixer and not cross-stacking is incorrect in my humble opinion. The reason for cross-stacking is to achieve improved consistency in cooling the dough balls AND to eliminate the formation of condensation within the dough box due to the dough being warmer than the ambient temperature in the cooler. It's just a matter of basic physics.

[Re: A Couple of Dough Management Questions](#)**1481**

With 1Kg. of flour weight you will need to use approximately 3.75-grams of IDY or 5-grams of ADY when using the dough management procedure I've described. 7-grams would be WWAAYY too much.

[Re: Pizza dough - 2 and 3 days cold ferment](#)**1482**

There's a reason why it is highly suggested that flour not be consumed raw. It's a miracle that this doesn't happen more than it actually does when you consider how wheat is handled and processed into flour.

[Re: GM Unbleached AP Recall](#)**1483**

Forget the "window pane" test unless you're planning to make bread. If the dough is too sticky for you to easily handle just lightly oil your hands. You only need to mix the dough until the lumps are worked out of it, bio-chemical gluten development will take care of the rest for you.

After mixing the dough the temperature should be in the 70 to 75F range (achieve this by adjusting the water temperature). After mixing, immediately scale and ball, place the dough balls in your fermentation containers or lightly oil the dough balls and place in individual Food Saver plastic bags (like bread bags) DO NOT use Zip-Lock bags. We have discussed

how to use the plastic bags many time here so a quick search will give you full details on how to do it if you wish to go that route.

Be sure to lightly oil the top of each dough ball after placing it in the container and leave it uncovered for at least 2-hours, then apply the lid for the remainder of the time in the fridge.

When ready to usd the dough remove from the fridge at least 2-hours prior to use time. You want the dough to warm to an internal temperature in the 55 to 60F range before opening, once the dough has reached this temperature it will remain good to use for a period of 2 to 3-hours depending upon temperature.

[Re: What can cause dough to be too stretchy? 1484](#)

JPB;

Bleed through can be a problem if you are stretching the dough very thin and not applying a light film of oil to the skin before saucing. It can be a problem resulting in a gum line on just about any type of skin/crust if you allow the dough to set for an extended period of time after saucing (again lightly oiling the dough helps here too). My dough weights for a 12-inch pizza go as low as 9.5-ounces and I've never had an issue with bleed through even when the pizzas are staged for a few minutes prior to going into the oven (this is with a decent sauce that isn't separating), and when I'm using fresh tomato slices as I typically do at this time of the year I ALWAYS lightly oil the dough skins prior to application of the tomato slices.

NOTE: Bleed through tends to be more of a problem with doughs that do not contain any oil/fat that with doughs that contain 1 or 2% oil/fat, this is because the oil in the dough helps to prevent the migration of moisture from the sauce/toppings into the dough before, during and after baking.

[Re: Sauce bleed -through 1485](#)

Agreed, more information would be useful, but also keep in mind that this is a common problem if the dough is not being opened correctly. be sure to stretch the edges of the dough as well as the center section, failure to do so usually results in an overly thin center section. I have some video footage of how to open a dough ball shown on my web site <www.doughdoctor.com> that may be helpful.

[Re: thin spot in my dough when stretching 1486](#)

Just make sure you ball the dough immediately after mixing (finished dough temperature 70 to 75F), and leave the containers OPEN for at least two hours after placing them into the fridge, then lid. It is suggeated that you lightly oil the top of each dough ball after placing in the fermentation container as this will prevent the dough from drying out during the time its uncovered. When you remove the dough from the fridge for final use allow the dough balls to warm to an internal temperature in the 55 to 60F/12.7 to 15.5C range before beginning to open them into skins. Once the dough balls have reached the target temperature range they should remain good to use for a period of 2 to 3-hours. Just remember to keep them cover to prevent drying after you remove them from the fridge.

[Re: Pizza dough - 2 and 3 days cold ferment 1487](#)

You should be fine with 1 to 2% oil. It will promote improved/greater oven spring and flavor in the finished crust.

[Re: Oil in dough 1488](#)

?????? ???

[Re: Sauce bleed -through 1489](#)

I didn't see any mention of finished dough temperature which has a very high probability of being another variable, and one which has a significant impact upon the amount of fermentation the dough will receive in any given period of time. If the dough was warmer it could account for the difference, additionally, the 3-hours warming period after CF could also be a contributor. As for the differences in yeast, if the CY was fresh and used at the correct substitution level I wouldn't expect any issues, but if the CY was not properly stored or old, or used at the incorrect substitution level for ADY it could be a contributor. By the way, the correct substitution of CY for ADY is twice as much CY as ADY.

[Re: What can cause dough to be too stretchy? 1490](#)

The sauce gets cooked on the pizza during the normal baking process so there is no need to cook the sauce prior to application on the dough skin. Some like to "bloom" their herbs, if that's the case just put the herbs in a little oil and lightly heat then add to the sauce and stir in. If you like the aroma of the sauce when it's being cooked just remember that those aromas are lost forever and will never be enjoyed as part of your pizza flavor profile. Plus cooking the sauce prior to use leaves the door open for something to go wrong during the cooking process, like scorching the sauce, when this happens it doesn't take much to ruin the sauce.

[Re: Cooked Sauce yuk! 1491](#)

If you're looking for a way to make your bread softer and maybe extend the shelf life by a day or so the oldest trick used by bakers to create a softer bread with improved shelf life characteristics is the use of mashed potatoes/potato flakes in the dough. Typically, 5 to 10% dehydrated potato flakes is all that's needed (remember that potato flakes will require an increase in dough absorption equal to about 2.5 times the weight of potato flakes being added. We use 2.5% dehydrated potato flakes in pizza dough that was developed for use in Japan where they wanted a soft eating finished crust. A couple of things to keep in mind, the addition of potato flakes to the dough will increase crust color development and be sure to use non-sulfited potato flakes as the sulfites (added to prevent the potatoes from oxidizing to a brown/gray color) will also adversely impact the yeast activity. Overall, we have found very little real application for "emulsifiers" in pizza dough. The two main ones being used are SSL (sodium straeoyl lactylate) and DATEM (diacetyl tar taric acid esters of mono glycerides). Both of these act in a similar manner in both bread and pizza doughs as dough strengtheners (prevents/minimizes dough collapse as it is mechanically transferred to the oven for baking) and most importantly, in pizza dough it enhances oven spring by about 15%, but consider this, in bread that's 15% of a dough that has a height of about 115-mm while for a pizza crust that 15% of 2 to 3-mm for a thin crust or maybe 15 to 20-mm for a thick crust.....in pizza that equates to a 0.3 to 0.45-mm height enhancement for thin crust or a 2.25 to 3-mm height enhancement for a thick crust. The standard deviation in height for both types of crusts exceeds those enhancements! So why are they use? The answer is to ensure that the dough doesn't suffer total collapse at the hands of the consumer.

In my early years at AIB I did much of the applications work on the use of emulsifiers in different dough systems. By the way, try to stay away from using a high ratio cake shortening in any pizza dough, these specialized shortenings contain poly-sorbates aka "Tween" to enhance batter aeration of the batter, the insidious thing about the poly-sorbates is that water can be mixed into water in their presence, without physical agitation, this means that if used in the dough, the water released from the sauce/toppings can/will migrate directly into the dough to create a wet, pasta like gum line under the sauce thus destroying the textural

properties of the finished crust.

[Re: Bakingbusiness.com Article: Emulsifiers](#) **1492**

I had one of the old M-800 Hobart mixers back in the 60's and early 70's. If I remember correctly there is a
n oil fill cup located on top of the planetary mechanism. Also, be sure to lubricate the bowl lift mechanism and adjust the agitator to bowl clearance (use a nickel) to set the clearance. You might be able to get a schematic on it directly from Hobart Corporation in Troy, Ohio.

[Re: Grease commercial mixer](#) **1493**

Looks a lot like the old P.H Big Foot pizza.

[Re: Fast Casual Chain & Pizza](#) **1494**

No "rule" but there is a procedure.

- 1) Calculate the absorption for the amount (weight) of "00" flour.
- 2) Calculate the absorption for the amount (weight) of rye or whole wheat flour. For rye flour and whole wheat flour use 75%.
- 3) Add the two absorptions and this will be the total amount of water to add to the dough. Note: The actual, final absorption may need to be adjusted slightly, but this will get you close enough to make pizza on your first "go around".

When expressing the dough absorption in bakers percent divide the weight of water added by the total/combined weight of the "00" and rye or whole wheat flours and multiply by 100.

[Re: Flour Experimentation](#) **1495**

The dough management procedure is the same whether the dough is mixed by hand or machine.

[Re: Tom Lehmanns Dough Management](#) **1496**

Steven;

I will assume your room temperature is 70F. which is pretty normal, so you will need to use water at about 65F to achieve a targeted finished dough temperature on the 80 to 85F range. The easiest way to find the desired water temperature for a targeted finished dough temperature in the 80 to 85F range is to subtract the flour temperature from 145 which will give you the approximate desired water temperature.

[Re: Water Temp for NY Style](#) **1497**

It's not a case of "could it be the problem", it is the problem. Cold dough right out of the cooler will always bubble unless the dough has been specifically formulated for use in this manner. Why don't you just pre-open the skins, place them on pizza screens and store in a wire tree rack (covered with a food contact approved plastic bag) in the cooler? This way all you need to do to fill an order is to remove a skin, turn it off of the screen and manually clean it up a little (hand/table stretch) then dress it to the order and it's ready for the oven. Because of the greater surface area and reduced cross section the skin will have warmed sufficiently so as to reduce or eliminate the bubbling by the time you're finished dressing the skin, and if you want to go the "belt and suspenders" route, just dock the skin immediately before beginning to dress it.

[Re: Cross Stack and Seal](#) **1498**

Jared;

I'm confused over exactly what flour/flour blend you used. Was it whole wheat flour, was it rye flour, a blend of rye flour and whole wheat flour or a blend of "00" plus whole wheat and rye flour?

To answer your basic question, both whole wheat and rye flour have a significantly higher absorption than "00" flour and unless this higher absorption rate is accounted for either/both will result in a dry, stiff dough. By the way, both rye and whole wheat flour will have a shorter fermentation requirement than "00" flour.

[Re: Flour Experimentation 1499](#)

Q.J.:

Spot-on! There is also less head-space for the condensation to collect in. At the end of the day the sheet pans are also faster and easier to clean, not to mention the fact that they are significantly cheaper to purchase too.

[Re: Cross Stack and Seal 1500](#)

If your oven is of one of the newer generation air impingement ovens (less than 10-years old) it may bake pan pizzas at the same time and temperature as your thin crust pizzas. If your oven is one of the older designs start at 435F for 7.5-minutes and bench make from there.

There are just too many different designs of air impingement ovens as well as finger profiles to be more specific.

[Re: What temp and time? 1501](#)

One trick that will work well in high volume situations is to use aluminum sheet pans. Place the dough balls onto the sheet pans and lightly oil the top of each dough ball, then slip a food contact approved plastic bag over the entire sheet pan, pull the bottom of the bag up over the first row of dough balls then pull the top down and tuck it under the pan. This works quite well and is commonly used in commercial pizzeria applications. The plastic bags can be reused a number of times too. Just be sure to use a plastic scraper to lift the dough balls off of the pan as a metal scraper will gouge the aluminum sheet pan. The best way to store the sheet pans is in a rolling vertical rack with a 5-inch shelf spacing.

[Re: Cross Stack and Seal 1502](#)

That would make a lot more sense :-D

[Re: Yeast % 1503](#)

Are you sure about those dough weights? They seem pretty light to me for those sizes. I've never been able to open one pound of dough to much more than 30-inches and at that it was too thin for making a decent pizza in my opinion. For a 40-inch pizza I would be using something closer to 6# of dough as opposed to a little over one pound. Am I missing something?

[Re: Yeast % 1504](#)

Plastic Food Saver bags! They work better than dough boxes, a lot cheaper too. If you will search back in the archives (not very long ago) we had quite a bit of discussion on this very topic.

[Re: Dough trays - cheaper alternatives? 1505](#)

Some commercial wood fired ovens will have decks 6 to 8-inches thick which hold a LOT of latent heat. The downside is that ours took 3-days to reach full operating temperature from a cold oven which is a real pain. The one thing that I got out of it is an appreciation for a dual fuel (wood and gas) oven. The gas is used to maintain

an idle temperature during the night and on any days that the store might be closed while the wood does the work during business hours. Back when all of our ovens were either wood or coal/anthracite fired there was good reason to live above the shop if you were a baker or pizzeria operator.

[Re: Manage floor temp w many bakes](#) **1506**

When was the last time you saw prime rib advertised as being fast baked/roasted? Baking develops flavor, just try a pizza before and after baking to prove this to yourself. A longer/slower bake for the type of pizza being made will always have more flavor than one that is baked as fast as possible. Sometimes it's only a matter of a few seconds more bake that makes the difference between a good pizza and a great pizza. Case in point, one of the major box pizza chains has an OK pizza but if they would bake it 30-seconds longer it would be a much better pizza all around, I guess corporate feels that they would lose too much business if they baked their pizzas for 30-seconds longer, you can only wonder if they ever looked at the other side of the coin?

[Re: World record for fastest bake](#) **1507**

If you will provide us with your present dough formula and procedure I will be glad to change it up to produce more of the characteristics which you are looking for.

[Re: Not NY Style dough formula please](#) **1508**

Yael;

I hope there ain't any shakin' going on while you're there.

Got a little shaky when I was there last.

[Re: Cake yeast ?](#) **1509**

It's reaqllly hard to say what the issue might have been but it might indeed have been the difference in oven temperature or how the pizzas were actually baked between on the screen and on the deck. When on the deck even just a few seconds can/will make a significant difference. I've got a hunch that that's where the issue was at.

[Re: Same dough and yet, hmmmm?](#) **1510**

Moose;

Are you using "exotic" hardwoods? From the picture it looks like maybe blood wood, tiger wood, maple and possibly ebony? In any case BEAUTIFUL!

[Re: pizza cutting boards?](#) **1511**

Yael;

I've worked in China (Chengdu) and know what you are talking about, in a case like that what I did was to simply add the IDY directly to the dough after it had been mixed to a point where it had just come together in a mass. All it needs after that is at least 5-minutes of mixing and it's good to go.

[Re: Cake yeast ?](#) **1512**

Compared to your cutting boards it must look like I'm cutting my pizzas on a rock! Great idea with the long one, the pizzas should remain hot a little longer on the wood board than on a serving tray when multiple pizzas are the order of the day. Now, the multi-colored one, my personal opinion, is that it's GEORGOUS! :drool: :drool: Makes my plain maple board look like a stone!

Well done!

[Re: pizza cutting boards?](#) **1513**

Let's see;

Compressed Yeast/Fresh Yeast/Block or Brick Yeast/Wet Yeast/CY

Disadvantages:

- 1) It must be kept refrigerated at all times.
- 2) It has a very limited shelf life, and you may not know how it was stored or how old it is when you buy it.
- 3) The amount that you use one week will likely be different from the amount needed the following week due to normal deterioration of activity.
- 4) Must be kept separate from salt and/or sugar.

Advantages:

- 1) Like Craig said "It sounds cool".
- 2) Can be added directly into cold water without issue.
- 3) Can be added to a machine mixed dough just as it is.
- 4) Lower cost if you are buying it by the pallet load and you are reasonably close to the point of manufacture.

Sorry, I really can't come up with many good reasons for using CY over IDY for most applications.

[Re: Cake yeast ?](#) **1514**

I might add that your dough ball count per box appears to be a bit high for the size of dough box you're using. There should be a minimum of a 1" space around each dough ball.

[Re: Longer fermentation in room temp](#) **1515**

All of my peels are from <MrPeel.com> They WILL ALWAYS warp if NOT handled properly.

I also have a peel from <portionpeels.com> which I like a lot as it has lazarus burned circles on the top side to help size and keep your pizzas round. I believe their peels are also from Mr. Peel.

- 1) Wipe the new peel with mineral oil over ALL surfaces. This will help to seal the wood.
- 2) NEVER/NEVER/EVER wash your peel. Wipe it with a slightly damp towel if it needs cleaning.
- 3) Over time your peel may develop rough spots, these are easily removed by LIGHTLY sanding with a 220 or finer grit sand paper, and then resealing.
- 4) Periodically wipe your peel down with a little mineral oil.
- 5) Remember, wood peels are prep peels, they are not meant to remove pizzas from the oven.

[Re: Basic questions](#) **1516**

Michiel;

A good temperature to begin opening the dough balls into skins is 60F when making pizzas at home. What kind of yeast are you using ADY, IDY or CY? In any case, when mixing the dough by hand as you are the yeast should be suspended in the dough water. A good procedure is to add water to the bowl, add the yeast (if ADY or IDY it will need to be hydrated/activated in 100 to 105F water first), CY can be added directly to the cold dough water. Then add the salt and IMMEDIATELY add the flour, mix until the flour is hydrated then add the oil and following your normal mixing procedure from there.

[Re: I don't like my pizza's.](#) **1517**

It's a lot easier to open the skin and place it onto a wood prep-peel, then dress it as

desired and peel it into the oven. Fine corn meal, semolina flour or rice flour are all good for use as a peel dust.

[**Re: Basic questions 1518**](#)

Yes, it's a good idea as it will prevent the lid from being blown off due to pressure build-up in the container.

[**Re: gooey dough 1519**](#)

My suggestion is to use 0.5% ADY which should be hydrated/activated in about 5 times its weight of water at 100 to 105F.

Adjust the temperature of the remainder of the water to give you a finished dough temperature in the 75 to 80F range (favoring 75F).

To address your peel dust issue please provide your complete dough management procedure.

[**Re: Basic questions 1520**](#)

Michiel;

These are my suggestions;

Reduce the salt to 2% (this will allow for slightly more fermentation within your 24-hour period of time.)

Eliminate the semolina flour and replace with your regular white flour. (semolina flour tends to make for a tougher, more elastic dough).

When you're getting ready to open the dough balls into skins you want to allow the dough balls to warm to 55 to 60F before opening the balls into skins. Allowing them to get too warm can result in the dough becoming too bucky/elastic.

Let us know how this works for you. One other thing: Try to target a finished dough temperature in the 70 to 75F/21.1 to 23.9C range.

[**Re: I don't like my pizza's. 1521**](#)

Huh? First time I've ever heard that about malt syrup. Malt, whether dry or in syrup form comes in two flavors, diastatic (enzyme active) and non-diastatic (non-enzyme active). Non-diastatic malt is used in the same way that sugar is used with one significant difference, it can provide a flavor other than sweet. At low use levels the flavor is said to be slightly "nutty" while at higher levels (above 3%) the flavor imparted is more like that of malted milk balls (candy). Diastatic malt (usually in the dry, powder form) is used at much lower levels, typically from 0.25 to as much as 0.5% depending upon the Lintner value so it is never used at levels high enough to contribute a flavor. The diastatic malt is a source of alpha amylase enzyme which converts wheat starch into sugars which can be metabolized by bakers yeast. Since this action takes place over time it is commonly used to support long dough fermentation times. It can also contribute to crust color development too as the residual sugars produced will contribute to the browning reaction during baking. Since the starch component of the flour is implicated with the staling process, many commercial bakeries will add diastatic malt to their dough formulations to help with reducing the amount of starch present (it's hydrolyzed into sugars) which in turn helps to provide for a softer, slower to stale finished bread. When an excess amount of diastatic malt is added to the dough formula the dough will become more and more sticky over time which can make the dough especially difficult to handle during the dough forming stage. This stickiness is impossibly to address and has been known to gum-up bread and bagel forming equipment.

I've never heard of any form of malt being associated with making stronger doughs or affecting the dough texture aside from stickiness, but at high levels it could

easily hydrolyze sufficient starch (starch carries only a small amount of the water prior to baking) which will release the water being carried by the starch to provide for a slightly softer dough, maybe that's what you are seeing? But at levels like this you would also be experiencing significant stickiness in the dough at the same time.

[Re: First time with diastatic malt](#)**1522**

In addition to reducing the dough absorption you will also want to NOT lid the containers right away. Instead, lightly oil the dough ball(s) and leave them UNCOVERED for at least 2-hours after placing them into the fridge, this will allow the dough balls to cool without the formation of condensation in the container which I am sure is contributing to the sticky dough condition. After the 2-hour period (uncovered) apply the lids BUT make sure there is a small hole in each lid to vent off any gas formation inside the container. You could also just place a piece of aluminum foil over each container and LOOSELY crimp the foil to the container.

[Re: gooey dough](#)**1523**

You're not going to get the same flavor or textural properties with a 6-hour dough that you would get with a 20-hour cold fermented dough. So now that you have the "ingredient", make your dough and give it the usual 20-hours cold fermentation.

[Re: Rise Time](#)**1524**

I think Amolapizza's suggestion to just keep the dough in bulk longer is an excellent one. When you scale and ball a bulk dough it has a similar effect to re-ball a dough (tightens it up and re-strengthens it). If your flour has the strength to tolerate the additional fermentation this approach might be your best bet. If you should find that the dough is too soft and sticky this would be an indication that you have exceeded the fermentation tolerance of the flour, if that's the case your best bet might be to further reduce the finished dough temperature by utilizing some or all ice water in the dough formulation.

[Re: Longer fermentation in room temp](#)**1525**

Actually, putting the torn/peeled mozzarella on this way presents the side with the greater surface area to the heat so the moisture has a greater surface area from which to evaporate. Physics #101.

[Re: FRESH MOZZARELLA ON ROMAN PIZZA: WATERY BASE???](#)**1526**

From the looks of your pizza you're struggling to open the dough. Please provide details on your finished dough temperature and dough management procedure, this is where the flavor and texture of the finished crust are largely developed and the dough is conditioned for opening without dough memory/snap-back.

[Re: I don't like my pizza's.](#)**1527**

Where on earth did you get the idea to allow the dough to warm to room temperature before using it? I always say to allow the dough to warm AT room temperature until it reaches 50 to 55F (50F for use in a pizzeria). Doing this will not create a gassy dough ball and it will give you about a 2.5 to 3-hour window of time to use the dough balls from the time they reach an internal temperature of 50F. If when doing this you still have a gassy dough we will need to look at your finished dough temperature. Your room temperature of 25C/77F is pretty typical for a pizzeria so it's not a problem at all.

[Re: Question for the Dough Doctor](#)**1528**

Because I'm familiar with the Eurobib as they are at Pizza Expo, but when it comes to spiral mixers, buy whatever you're comfortable with, I've yet to see or hear of a bad one, with that said, take heed if someone takes issue and complains that they have actually used a bad one, you will have narrowed the field of selection down by at least one.

[Re: Kitchenaid Mixer has burnt out - What can I use for Neapolitan pizza dough?1529](#)

Your intuition is correct as there just isn't any significant call for it outside of the commercial market. With that said, you can make a fair to middlin' version of it very easily. Just use and U.S. household butter, freeze it and shave it into strands/ribbons like you would a hard cheese or chocolate. Immediately put the shaved butter back into the freezer for at least an hour, remove from freezer and place between two pieces of waxed paper, tap with the handle of a table knife to break the frozen butter into pieces 3/16 to 1/4-inch in size. Immediately place back into the freezer until ready to use. Use a dough absorption of about 56 to 58%, mix until the dough just begins to smooth out, then add the frozen butter chips and mix JUST until they are fairly well incorporated (better to error on under mixing than over mixing). Remove dough from mixing bowl, roll out to about 1/2 to 3/4-inch thickness, give a 3-fold and place into the fridge to rest about an hour, or until the dough can be sheeted again the same way. Rest the dough in the fridge after the second 3-fold for 4-hours, then scale into desired weight pieces (I an inverted coffee can to cut circles), pin out the cut circles of dough to full diameter, the skins can be rested for holding in the fridge or used immediately if the temperature of the dough is at 50 to 55F which it usually is after pinning it out to full diameter. If you store the full size skins in the fridge you will need to allow them to warm to 50 to 55F before use, it won't take very long.

By the way, if you want to read up on how the bakers did this before the advent of hard fat flakes study up on the "Blitz" method of making laminated pastry.

Tom Lerhmann/The Dough Doctor

[Re: What Hydration Makes it "Cracker"?1530](#)

I've never tried them, but don't let that stop you from giving them a try. When I'm working with fresh mozzarella I slice and layer between clean bar towels for about an hour prior to use. You're over thinking this, it'll give you a headache. :)

[Re: FRESH MOZZARELLA ON ROMAN PIZZA: WATERY BASE???1531](#)

I agree with Jeff. In my world dough that has been properly managed for cold fermentation really doesn't need to be degassed or re-balled, but room temperature fermented dough can be a totally different story. Dough that has been bulk fermented at room temperature should be "punched" when it reaches its maximum height and just begins to recede a little. Otherwise, the dough will be naturally degassed when you scale and ball it. Dough balls that are fermented at room temperature and become over fermented, for whatever reason, are usually re-balled at the soonest opportunity, this re-balling significantly tightens the dough ball necessitating the need to ferment the dough balls for additional time to allow them to loosen up for ease of opening and reduce dough memory (snap back) of the opened skin.

Note:

In bread production, when a bulk dough (regardless of the temperature at which it is fermented at) reaches its "first full rise" (this is where the dough ferments to its maximum height and then begins to recede on its own as described above) it is deemed to have received 2/3 of its optimum fermentation so after being punched,

the dough is given the final 1/3 additional fermentation time before it is scaled and balled. Since pizza doesn't abide by the same rules as bread you have a lot more latitude in fermenting the dough with regard to time and temperature BUT if you venture into the over fermented dough territory, when you go to open the dough balls into skins you will find the dough balls tough and bucky and impossible to open by any means.

[Re: When to degas the dough?1532](#)

I'm still seeing the same thing. Typical to what we get when using hard fat flakes. Where the fat flakes melt out a void is developed which forms the oval shaped void called a "fish mouth" where there are no fat flakes to melt out the crumb structure consists of smaller round shaped cells. I think we're looking at the same thing just calling them by different names.

[Re: What Hydration Makes it "Cracker"?1533](#)

A trip over to the local metal salvage yard can turn up some real treasures on a good day.

[Re: Fabricating your own baking steel1534](#)

It all depends upon the application and type of pizza I'm making. If it's more of an artisan (I'm using that term loosely) I prefer to use the fresh, ditto for New York and Neapolitan, but if it's for most others as well as DELCO I usually opt for a shredded low moisture mozzarella.

[Re: FRESH MOZZARELLA ON ROMAN PIZZA: WATERY BASE???1535](#)

Cut thin and place between towels to drain as best you can or peel it like an orange (that's how I do it) and place the pieces on top of the pizza as the last ingredient. In some cases with home-made cheese we find it necessary to apply the cheese about half way through the bake.

[Re: FRESH MOZZARELLA ON ROMAN PIZZA: WATERY BASE???1536](#)

Yes, you only activate the ADY in approximately five times its weight of water, never all of the dough water as you are indicating. Once the ADY has been hydrated and activated it can safely be added directly to ice water if necessary.

[Re: Autolyse1537](#)

John/Pete-zza;

Sorry, I don't see any "pin holes" I only see a laminated cell structure with some very classical "fish mouthing". Maybe what you are calling "pin holes" is what I'm seeing?

Your dough looks very much like the dough that we make using hard fat flakes. When it comes to mixing a cracker type crust we have had our best success using a planetary type mixer with a pastry knife attachment. With this attachment the mixing time is significantly longer than with a regular dough mixing attachment but it does a great job of blending the ingredients into a homogeneous mass while distributing the fat evenly throughout the dough. This is the preferred attachment for making pie dough too so it's no wonder that it works well in this application. The least effective mixer for making the cracker type dough is the spiral mixer, they were never designed for cutting and blending which is what is required for making a cracker type dough.

[Re: What Hydration Makes it "Cracker"?1538](#)

If you are going to be mixing doughs on a regular basis, my advice is to "bite the

"bullet" and buy a spiral mixer. It will most likely be the last mixer you'll ever need to buy (unless you need a larger mixer). Google (Eurodib dough mixers) and take a look at the Eurodib Model LM20T. It's priced at just under \$1,000.00 but as an investment it will be cheaper than several smaller mixers that you may burn-out over the years. This mixer also has the added feature of an 8-Kg. dough capacity while mixing smaller doughs like a "walk in the park".

[Re: Kitchenaid Mixer has burnt out - What can I use for Neapolitan pizza dough?1539](#)

Peter;

I think too many people are too wrapped up in dough formulation as a distinguishing feature between thin crispy and cracker. We found that not to be the case at all, you can make a very good cracker type crust using 2% total fat if you are willing to go the lamination route as you can get with 4 to 8% fat by mixing a shaggy dough (about 45-75-seconds). When we did the development work back in the 70's we found that a plastic shortening worked much better than an oil in this application as it did not soak into the flour thus destroying any ability to create crispiness. When we did the development work we looked at how saltine crackers are made (under mixed using a spindle type mixer) and then also looked at how a long to medium flake pie crust is made (has a lot of the characteristics of a cracker type crust) and used that as the basis for our development work. More lately, in the 90's we were looking at the use of hard fat flakes in very under mixed (shaggy) doughs to achieve this. While the results were pretty good we thought the crust was more like that of a laminated croissant than what we were looking for. In my archives I've got the entire procedure using the hard fat flakes captured on a DVD. We ended up using this approach when we were asked to develop a dough for use in making pizza cones where it worked beautifully with just a little modification to allow it to be pressed into the desired cone shape while still retaining the desired flaky characteristics in the finished crust/cone.

[Re: What Hydration Makes it "Cracker"?1540](#)

One of the characteristics of bread staling is loss of flavor. Are you sure this is not what you are picking up on? Bread staling takes place most rapidly at temperatures between 20 and 50F which is why we don't store bread in the fridge (home freezers are not much better either), if you want to make croutons just slice the bread and store in the fridge overnight and you'll have nice firm bread on the following day.

[Re: Soapy taste, leftover pizza? 1541](#)

ADY should be activated in 100 to 105F water to prevent glutathion from leaching out.

[Re: Autolyse1542](#)

Thin crispy style crusts are indeed sheeted as are cracker style crusts but the absorption is a bit higher, usually around 45% along with a longer mixing time as previously noted. Thin crispy crusts tend to be more dense than cracker style too. We used to say that you know when you're eating a pizza made on a cracker crust when you have crumbs in your lap. A number of years ago we saw commercial attempts at this type of crust, Schwan's probably had the most visible as it was called their Italian Pastry Crust Pizza. While the crust appeared to be laminated it really wasn't, instead it was made using hard fat flakes mixed into the dough to give it a laminated and cracker like appearance. So, what does a real cracker crust look like? It looks like a saltine cracker and it eats somewhat like one too. For those

who are old enough to remember, this is the type of crust that put Pizza Hut on the map, it's the original thin crust that they had back in the early 60's, what they have now is more of a thin crispy style. A good example of thin crispy is that made by the Pizza Shoppe (Kansas City) as well as any number of pizza buffets our local Pizza Ranch has a fair to middlin' version of a thin crispy crust.

The only place that I can think of off hand that might still make a cracker type crust (they use to at least) is Incredible Pizza (Springfield, MO.)

[Re: What Hydration Makes it "Cracker"?1543](#)

Are you pre-activating/hydrating the ADY prior to addition or just adding it dry?

[Re: Autolyse1544](#)

Cracker type crusts are typically made using a dough absorption somewhat less than 50% and a mixing time of 2-minutes or less. The dough is handled much like a long flake pie crust and has to be formed using a dough sheeter/roller as it's too tough to open any other way. When the dough is mixed longer to form a homogeneous dough mass the end result will be a thin crispy crust as opposed to a cracker type crust. We have had previous discussion on making cracker type crusts. If you have ever visited Incredible Pizza you have had their cracker type crust. It holds up really well on a buffet line.

[Re: What Hydration Makes it "Cracker"?1545](#)

One of the characteristics of salt is that it tightens the dough, if you omit the salt from the dough formula you will always get a softer, more slack dough consistency than if the salt were present at normal levels.

[Re: Starter is not dissolving in water1546](#)

Craig;

Bread type flours will typically use a combination of benzoyl peroxide for bleaching and ADA for chemical oxidation/maturing of the flour. ADA is too slow acting for use as a bleaching agent. Chlorine gas is more typically used in some pastry flours but mostly in high-ratio cake flours where it plays a VERY significant roll in functionality of the flour in making high-ratio cakes.

[Re: Bleached vs unbleached?1547](#)

It appears that you might be washing the gluten from the flour in your starter. When I make a starter I always use at least 75% absorption in the starter and then add it to the dough as an ingredient without trying to suspend it in the water.

[Re: Starter is not dissolving in water1548](#)

Three questions which I have are:

- 1) What was the finished dough temperature?
- 2) How did you make the poolish? Possibly 20% is too much.
- 3) What was the total dough fermentation time between mixing and use of the dough?

[Re: Autolyse1549](#)

Not wrong, just differently. It may not be just one thing but instead an accumulation of several little things/differences that is responsible for the difference. Mixers, water, temperature are but a few things that can add up to make a difference.

[Re: Bleached vs unbleached?1550](#)

Fine corn meal works well as does semolina flour or even rice flour all make for a good peel dust.

[Re: How to get pizza into oven?1551](#)

I've done this two ways, maybe one of them will work for you.

This is for a small oven.

Using your metal oven peel, remove the entire pizza from the oven, immediately slip the peel under the pizza removing it from the screen and transfer it back into the oven.

The other method involves the use of long handle tongs, slide one side under the screen (you may need to flatten one side using a hammer) grasping the screen, then pull the screen out from under the pizza leaving the pizza on the oven deck. If the oven is sufficiently large you can simply use a spinning peel to lift the pizza off of the screen and place it onto the oven deck then remove the empty screen.

[Re: Which kind of dough should we use with a pizza screen ?1552](#)

Bleaching and oxidation of flour are two entirely different processes. Chemical ageing of the flour is accomplished using Maturox aka ADA (azodicarbonamide) while bleaching is done using benzoyl peroxide and sometimes chlorine gas. The flour is milled the same whether it is bleached or not.

[Re: Bleached vs unbleached?1553](#)

When vegetables become our main source of protein the world will be at the whims of Mother Nature in a big time way, specific crop types will become dominant and more widely grown thus lowering resistance to insects, fungus and a host of other insidious attacks suffered by plant species, when this happens we will have a much larger audience competing for a smaller "piece of the pie", and that ain't going to paint a pretty picture. We saw some of this very thing happen just a few years ago when there was a world wide shortage of wheat, remember that time? If not let me remind you, flour (when/if available) was selling for nearly \$50.00 a bag! The flour that was available was flour by name only, not the best by any stretch of the imagination, but it was "flour". Much of Asia has transitioned from rice to wheat since the 1960's so the "audience" was size able to say the least. There was an essentially catastrophic wheat crop failure in the U.S., poor planting and growing conditions in Canada, Drought in Australia and poor harvest conditions in Mexico and much of Latin America. Even Russia suffered the same failed crop conditions! What many people don't realize is that the world wheat surplus, which is usually measured in weeks or months was down to being measured in days and finally in hours. There was fear of civil unrest due to food shortages world wide. Yes, there were other crops available for consumption but their prices had sky rocketed and they were not being grown in sufficient quantity to off-set the wheat shortage, plus don't forget the gluten equation, there are a lot of foods that need gluten. So why not just use gums to replace gluten? Great idea, only one problem, since everyone else thought of that too the cost of ALL types of gums/binders had become cost prohibitive and non-available, we like to refer to this as the domino effect. My point is, if it can happen to wheat it can happen to any other plant. A lost plant crop can be easily converted to animal feed to grow live stock a a source of food, but eating corn/wheat/ milo/bean crop failure is not my idea of fine dining, I'd rather it be fed to the live stock first and then eat the live stock. Just my humble opinion.

[Re: The End of Meat ?1554](#)

Joel;

I've been retired from AIB for 5-years now. I put in just shy of 50.

[Re: Best way to prepare for multiple pizzas](#)1555

I used to tell my students that the ingredients are like bricks and mortar and you're the brick mason. Depending upon how they are assembled you can make a privy or a castle. It ain't the ingredients that makes for a great pizza, it's how they are put together and managed that makes the difference. To answer your question though, the dough formula that we used for over 35-years as our "base" dough formula for making both thin and thick crust pizzas with a refrigerated dough ball life of 3 to 4-days is as follows:

Flour (12 to 12.8% protein content) 100%

Salt: 1.75%

Sugar: 2%

Oil: 2%

IDY: 0.375%

Water: 62%

We used the delayed oil addition mixing method as well as my dough management procedure for refrigerated dough. Pizzas were baked in a variety of different ovens, B.P Deck, Marsal Deck, Lincoln Air impingement, XLT Air impingement, WoodStone Wood Fired, a TurboChef and an Air Deck to name but a few.

[Re: How should I go about this?](#)1556

There is a commercial product that some pizzerias and large wholesale manufacturers use that looks a lot like bread crumbs, it's called Pizza Crisp.

[Re: Breadcrumbs](#)1557

Yup, once the ADY has been hydrated and activated it can be safely added into the cold water without any problems.

[Re: Which kind of dough should we use with a pizza screen ?](#)1558

If it were me, I'd round the flour weight off to 50-pounds then calculate the ingredient weights from the percentages that you have listed. Note: When based on 50# of flour the water at 63% calculates out at 31.5-pounds divided by 2.2 = 14.3 L. (less than your 14.9 L.). But still using the original 49.97-pounds of flour weight 49.97 X 63 (press the "%" key) and read 31.48-pounds in the display. 31.48 divided by 2.2 (pounds in a liter) = 14.3 L.

[Re: How should I go about this?](#)1559

Joel;

0.6% IDY is a bit on the high side and could certainly contribute to over fermented/blown dough. I suggest reducing it to something in the 0.3 to 0.4% range.

Wow! You're right in my back yard!

Send me an e-mail with your contact information and I'll try to get down to see you (35-miles away).

<thedoughdoctor@hotmail.com>

[Re: Best way to prepare for multiple pizzas](#)1560

Ditch the ZipLock bags, instead go with Food Saver bags. They're a LOT cheaper and they will work much better in this application.

[Re: sufficient humidity for dough retarder/proofer?](#)1561

Screens are not a problem at high baking temperatures IF there is a pizza on it.

The pizza will absorb heat thus protecting the screen, but an empty screen in a wood fired oven can be a disaster. In the baking industry we have a similar problem with tin plated pans, tin melts at about 450F and we do a lot of baking in the 465 to 475F range so it's important to have dough in each and every loaf pan on the strap (in our case there were 5 loaf pans to a strap). If one of the pans went into the oven empty the tin would melt off of the empty pan destroying not just the pan but the entire strap of pans which was quite expensive.

[Re: Which kind of dough should we use with a pizza screen ?1562](#)

I can't answer your question on yeast amount as I don't know what type or how much you are presently using, but there is a lot more to over fermentation of the dough than too much yeast such as how you're managing the dough as well as the finished dough temperature.

All of that aside, here is what I'd do;

Use 65F water temperature (looking for a finished dough temperature in the 75 to 80F range).

Immediately after mixing scale and ball the dough.

Lightly oil each dough ball and place into individual plastic Food Saver bags (NOT ZipLock).

Twist the open end into a pony tail and tuck it under the dough ball as you place it into the fridge.

Cold ferment for desired time.

To use, remove from the fridge and allow to warm to 50 to 60F internal temperature.

Roll the bag down around the dough ball and invert over a floured surface allowing the dough ball to fall free from the bag onto the floured surface.

Open the dough balls into skins by your preferred method.

Dress to the order.

Bake.

Note: The dough balls will remain good to use over a 2 to 3-hour period of time once they reach 50 to 60F.

[Re: Best way to prepare for multiple pizzas?1563](#)

You will want to wipe it down/sanitize it between different applications. Before worrying about relative humidity you're going to need to figure out a way to stabilize the temperature. At 80% R.H. you're close enough to the dew point that any loss of temperature will result in condensation forming (you already know that). The problem with small boxes like wine coolers is that even once you get everything dialed in your dough box and dough will be cooler than the ambient in the box so you're going to get condensation forming on the dough and dough box surfaces, and if it cools the temperature in the wine cooler you'll get condensation forming on the inside surfaces. This is why, for the most part, the baking industry has moved away from using temperature & humidity controlled rooms for fermentation, instead they just control the temperature, prevent any drafts and lightly cover/drape the dough container (dough trough) to help capture the carbon dioxide formed during fermentation which will blanket the dough (green house effect) thus preventing moisture loss, also, keep in mind that the environment inside of the wine cooler will be HIGHLY caustic due to the acids formed during fermentation, it has a nasty habit of getting behind panels and into places where it will corrode anything that isn't high grade stainless steel.

[Re: sufficient humidity for dough retarder/proofer?1564](#)

To answer your screen question, screens can be used with any dough that will not

flow into the screen openings either due to high absorption, or the need to proof the dough on the screen (especially when combined with high dough absorption). As a general rule, 66 to 68% absorption is about the highest dough absorption you will want to use with a screen, this is assuming a fully dressed pizza. If you are making par-baked crusts you can get away using a higher absorption as there isn't the weight of the toppings pressing the dough down into the screen openings both prior to and during baking. Just make sure you season your screens well before using them, failure to do so can result in the dough welding itself to the screen during baking, and NEVER soak a seasoned screen in water, just wipe it clean and you're good to go.

As for your IDY question, DO NOT hydrate IDY in cold water, use only 95 to 100F/35 to 37.7C, water, failure to do so will leach out glutathione from the yeast cells resulting in poor yeast activity and inconsistently soft doughs. If you search back through the archives you will find significant discussion on both screens and their care and use as well as IDY. The only time you really need to pre-hydrate IDY is when mixing dough by hand or if machine mixing for less than 5-minutes, otherwise just add the IDY right on top of the flour and begin mixing.

[Re: Which kind of dough should we use with a pizza screen ?1565](#)

Correct, Norma and I spoke about this some time ago. They're about twice as big and a lot easier to use than the P-38 version.

[Re: What can opener do you use to open your #10 cans?1566](#)

The biggest down side to high absorption doughs is that it's really difficult to make a decent cracker type crust using high absorption values. :-D Aside from that, as you keep increasing the absorption the dough will eventually become too sticky to handle without using excessive amounts of dusting flour and all the collateral damage resulting from the excessive dusting flour, then too the dough will over expand during oven spring resulting in potential collapse. At some point you will see an impact upon bake time and temperature but more so than that will be a higher than normal, or desired, residual crumb moisture content resulting in a pizza that retains its crispiness for a time period measured in seconds. This is one reason why when we bake at very high temperatures crispiness takes a back seat. By the way, as moisture content goes up (especially over 68%) we need to bake at ever increasingly higher temperatures which means a shorter bake time and a less crispy crust or at least a crust which doesn't retain its crispy nature, then at some point we just can't bake out all the moisture and that's where the real fun begins.

[Re: Any "downsides" to a higher hydration dough??1567](#)

Food contact but probably not reheating. They're entirely different functions.

[Re: Soapy taste, leftover pizza? 1568](#)

Just be sure to wet the sand or it won't serve the intended purpose.

[Re: Hobart A 200 restauration1569](#)

First things first, it's important to know how you are mixing your dough, by hand or machine, it makes a difference.

[Re: ok- last question for a bit! Salt in the flour??1570](#)

From the picture, the dough appears as if it might be somewhat under absorbed. Add to that the small amount of yeast called for suggests the possibility that maybe there isn't sufficient yeast in the dough (the % is correct but is the actual amount added to the dough correct?). Remember, as you knead the dough you are

developing the gluten so the dough is becoming increasingly tenacious (rubbery), this is normal especially for a low absorption dough which it appears you might be working with. The first thing I would do is to increase the dough absorption by 5% to see if that provides for an easier to knead dough, you might need to further fine tune the absorption if you see some improvement at 5%. Even if the dough is a little tacky (not sticky) that's fine as it'll improve as the dough is developed and as it ferments. Let us know how this works and send a picture of the dough.

[Re: Any good recipes/techniques with these ingredients?1571](#)

Works out in the field but in the kitchen?

[Re: What can opener do you use to open your #10 cans?1572](#)

I always thought it was an instrument used to measure precipitation/rainfall? In the baking industry we have used graduated cylinders into which we put a measured amount of dough at 85F and tamped it flat, then placed it into a temperature controlled cabinet (90F) with a piece of foil over the top to prevent drying. The test was used to measure/compare the activity of yeast over a 3-hour period of time. Since all flours are different I'm trying to figure out how this would relate to assessing/determining the correct fermentation for any given flour. What am I missing?

[Re: Follow up on Pluviometer readings1573](#)

As a baking fat (one that is included in the dough formulation) soy bean oil at typical levels (2% and less) really isn't all that bad when pizza is consumed as a part of a healthy and varied diet, but when it's used as a frying fat the complexion changes significantly, in fact, frying doesn't help the nutritional profile of any fat or the food fried in it. This is not to say that we should avoid all fried foods, but we might want to think of them in moderation as part of a healthy diet. I'm in total agreement with what Peter said but I'd like to add that when you look at the animal diets from which conclusions are made the diets are always "HIGH" in whatever they are testing, for years we have always said that this is not realistic and at best it supports potential or trends not absolutes as many try to interpret the results of these studies. Again, let me state, moderation and variety are essential to a healthy diet. If there is anything that does worry me it is sprouts and spinach, two of my favorites, and baby spinach has just been involved in another recall again. :(

[Re: Soybean oil: Healthy or Harmful1574](#)

Ditto that opener for me too. I got mine at a sale many years ago. Never fails. I do suggest cleaning the top of each can prior to opening for sanitary reasons.

[Re: What can opener do you use to open your #10 cans?1575](#)

I totally agree, Neo. pizzas are probably the all time worst selection for a DELCO pizza. Their acceptable life is measured in single digit minutes.

[Re: Hybrid Dough - Delivery1576](#)

My reference to ml v/s grams is that "ml" is still a volumetric portion and subject to a certain amount of potential variation (especially when considering the small amount of flour being used), the difference would be small so I added the "Questionable but maybe". When I ran the bake labs at AIB we always used the smallest graduated cylinder possible when working in milliliters. The larger the cylinder the greater the potential for error either by eyeballing or due to residual water in the cylinder after pouring the water out. Working with such small amounts of flour is always difficult as you almost need an analytical scale. Whenever

possible we always weighed the water, yes there was residual water in the weigh container but at least it was a constant error which we could cope with.

[Re: hard dough that tears when kneading](#)**1577**

Adjust the water temperature used in making your dough to give you a finished dough temperature of 70 to 75F (favoring 70F). Ball the dough IMMEDIATELY after mixing, lightly oil the dough balls and place into individual plastic bags, twist the open end to form a pony tail and tuck it under the dough ball as you place it into the fridge (34 to 38F), allow the dough balls to ferment in the fridge for at least 24-hours (48-is better) before using. To use, remove from fridge, allow to warm to 60F, roll the bag down around the dough ball, invert the bag and dough ball allowing the dough ball to fall free from the bag onto a floured surface, open into a skin by your preferred manner, dress and bake.

This should eliminate the need to re-ball and give you an overall, better and more consistent product.

Following this procedure the temperature of your kitchen will have minimal impact upon the dough.

[Re: Work with pizza balls](#)**1578**

Ceramic just means that it has been hardened by application of heat (in a kiln).

[Re: Are these quarry stones ok to use at home?](#)**1579**

Without knowing how you're making your dough and more about the flour you're using I can only speculate.

1) Your dough needs more water (higher absorption).

2) Your flour is too strong.

3) Your scaling is off. You indicate 80-ml, not 80-grams, of water, perhaps that's your problem? Questionable but maybe.

Why are you not weighing the salt? It should be about 2.5-grams which is more than the ADY which you are weighing.

4) The ADY should be about 0.625-grams.

5) I don't see any mention of activating the ADY prior to addition to the dough, perhaps that is contributing to the problem.

6) What is the water temperature and what is the finished dough temperature?

Much of what you've described is indicative of an under absorbed and under fermented dough, there is nothing sacred about 64% absorption so don't hesitate to increase the dough absorption, all flours are different, some will require a higher absorption than others.

7) Are you using dusting flour to help with kneading the dough? If so it is highly possible that the dough is picking up sufficient dusting flour to really upset your dough absorption. Remember, with such a small dough size just 10-grams of dusting flour can through off your dough absorption by as much as 6% or more. I know this isn't much help but maybe it'll give you some insight into what the cause might be.

[Re: hard dough that tears when kneading](#)**1580**

The higher protein flours are used in hamburger and hot dog bun production for the resilience it imparts to the crumb structure. When made using low protein flour the crumb structure lacks resiliency and becomes somewhat crumbly.

In hamburger bun production, if you want to add seeds as a topping all you need to do is to lightly spray the surface with water and the seeds will stick just fine PROVIDING THAT YOU HAVE NOT ALLOWED THE CRUST TO BECOME DRY PRIOR TO APPLICATION OF THE WATER SPRAY. If the crust has dried a cooked

starch application will be your best chance to make the toppings stick after baking. To make the cooked starch just add 1-ounce of corn starch to 1-quart of water and heat just until it begins to simmer, allow to cool until warm (not hot) and carefully brush onto the top of the buns just before adding seeds, etc. The starch wash also imparts somewhat of a shine to the crust too.

[Re: Tom Lehmann's guide to burger buns](#) **121**

Sounds like it was what is referred to as a "long flake" crust.

This is where the fat is refrigerated until firm but not hard, it is cut into the flour until the fat pieces are about the size of cherries. The pie dough is then formed into pucks, placed on a sheet pan and covered to prevent drying, place in the cooler over night then brought out on the following day. They are allowed to warm AT (NOT TO) room temperature until the sough can be rolled to about 3/16-inch thick, fitted into the pie plate (pan), filled, top crust applied, sugared or egg washed and baked.

[Re: Tender Flakey Pie Pastry Crust](#) **122**

There are at least two documented cases of clostridium in vacuum packaged tortillas coming from Canada, that's two too many! Work that was done at AIB (American Institute of Baking) back in the 50's confirmed that clostridium can grow in bread stored in an anaerobic environment, this is reason enough for ME to take vacuum packaging VERY seriously. When I refer to just plain freezing I'm referring to non-vacuum packaging of the product and then placing it into the freezer for storage.

[Re: frozen/vacuum sealer pizza for delivery and pickup.](#) **123**

Just about any unmalted flour can be successfully used for high temperature pizzas.

[Re: New King Arthur '00' Pizza Flour](#) **124**

None, it will just show up as another ingredient at .5%, the sum of the percentages will also increase by 0.5% to 167.75%. That's one of the nicer things about working in bakers percent, since all ingredient weights are based on the total flour weight if you change the weight of any ingredient (except for the flour) everything else remains the same. If you were working in "true" percent if you change the weight of ANY ingredient the percent of ALL the others has to be recalculated.

[Re: Getting crust to brown without being to overcooked and hard.](#) **125**

Scott;

I've seldom ever really found it necessary to go with a dough divider as it's really pretty easy and accurate to scale the dough by hand like Walter said, it's the rounding that catches up with you, so hand scaling isn't all that bad but you can really "grease the wheels" with a dough rounder. By far, the most efficient method for hand scaling the dough it to cut it into strips (called ropes) and then use your cupped hand to work it out to about the same diameter along its entire length, then cut a piece off and weigh it, the idea being to find the length that gives the targeted weight, once you develop a feel for it this method can be VERY fast.

During our seminars two of us could scale and ball (using an AM Dough Rounder) 85# of dough into 10-ounce dough balls in less than 20-minutes. We used to make a challenge out of it to see how many pieces we could cut that were the exact targeted weight, my personal best was, I believe, seven dough pieces in a row. I might add that we only did this once a year so it wasn't like we were doing it every day either! We could also round (ball) the dough manually in under 20-minutes too

by using the two handed balling procedure (shown in my dough making video at <www.doughdoctor.com>) but I'll be the first to admit that it'll catch up to you sooner than later....give me a mechanical dough rounder!!!

[Re: Rounder and divders126](#)

Yael;

The problem with durum semolina flour has to do with the type of gluten it produces, a very tough and elastic gluten, to be sure. This is why it is mostly used for the production of pasta. It can help produce a crispy crust but at the expense of added toughness as the pizza cools off, like in a DELCO scenario. It's for this reason that we've always suggested to limit its use to not more than 25% of the total flour weight.

[Re: Quest for a tender neapolitanish pizza127](#)

Durum semolina does you no favors if your main concern is tenderness.

[Re: Quest for a tender neapolitanish pizza128](#)

There are, but you will need to change gears and look at bakery dividers (ram and knife). These are designed to degas fermented doughs for consistent scaling weights. The bad news is that they are large (even single and double pocket dividers are pretty large for a pizzeria) they're potentially expensive and they may not work well with weights much under about 10-ounces. Even the big wholesale manufacturers divide the dough prior to fermentation, they then round (ball) it and give it an intermediate proofing period just prior to final shaping (usually hot pressing). In other cases they will process the fermented dough on a stress free sheet and die cut processing line (think of processing 4,000-pounds or more of dough per hour before ordering one) which minimally degasses the dough while forming it into a continuous sheet from which individual pizzas are die cut and then usually go to an oven for par-baking, then to cooling and a trip through the finishing room where the par-baked crusts are dressed, then blast frozen, individually packaged, boxed, palleted, and placed into a holding freezer to await transportation to a distributor.

[Re: Rounder and divders129](#)

As long as you are at or above the 50 to 55F range you'll be fine.

[Re: dried out crust after parbaking130](#)

The somerset is a good unit and it works very well, too bad they staged the video using previously rounded dough balls...dumb mistake! The other rounder that I like a lot is the AM Manufacturing rounder, you wouldn't go wrong with either one.

[Re: Rounder and divders131](#)

Shrink wrapping and putting the pizza in a plastic bag are essentially one and the same. Airflow in a package? Go back and read the article referenced above by PIZZA_NOT_WAR and I think you will have both questions answered. A number of years ago I had a person contact me regarding a problem he was having, some of his packages were blowing up (bulging), his concern was how to find a gas permeable packaging material to allow the gas to escape!!! He didn't even recognize the potential of what he was for causing illness or worse! This is why I always recommend that anyone getting into anything more than just plain freezing ALWAYS have a microbiologist on staff. The question of the day referencing the issue cited above: Would you consume anything taken from a bulging can? How about a canned product taken from a jar with a domed lid?

[Re: frozen/vacuum sealer pizza for delivery and pickup.](#) **132**

No, your problem is due to collapse of the crumb structure resulting from insufficient baking of the crust. It is NOT a drying out issue. In order for the problem to be resolved you have to achieve an internal temperature of 185 to 190F to fully set the structure, anything less than that and the structure will collapse upon cooling. The idea behind par-baking is to achieve a full internal bake (185 to 190F internally) while developing a finished crust color that might be best described as being "sandy" in color. If you get too much color during the par-bake the crust will either get done too soon or it will get too much color when the pizza is fully baked. If you want to see an excellent example of something that is par-baked just take a look at those par-baked dinner rolls that you'll be buying in a few weeks to go with your Thanksgiving turkey.

The reason for using a screen under the skin during baking is because it helps to reduce some of the bottom heat (remember, pizzas ovens are designed to provide more heat to the bottom of the pizza than to the top during baking).

[Re: dried out crust after parbaking](#) **133**

Your case is not so uncommon where you are looking for a characteristic that you might or might not get so in that aspect it's always elusive. When this happens the issue is almost always attributable to some kind of inconsistency in what is being done. In reading through your formula and procedure it appears to me that your are not being specific on times and temperatures (remember the acronym "GIGO" garbage in garbage out. In this case it's "IIIO" inconsistency in inconsistency out. You're on the right track by buying a thermometer so you can document things like flour temperature, room temperature, water temperature and finished dough temperature. By tracking these you will be able to develop a chart for determining the correct water temperature to use to achieve your desired finished dough temperature. This is vitally important as you are bulk fermenting and just a few degrees difference in finished dough temperature can make a big difference in the total amount of fermentation the dough received over the following 18 to 20-hours.

Which brings me to times, pick a time that works for you and then just be CONSISTENT, use that time fermentation time consistently. You will also want to be measuring the dough temperature when you scale and ball it and again when you go to open it into a skin. While the 2-hour difference between when you begin opening the dough balls until you finish opening them may not seem like much, it can make a HUGE difference in the finished crust depending upon the temperature of the dough balls at the time when you begin opening them. I think after you begin addressing these inconsistencies your results will be much more consistent and you will either have your 10 or possibly 11 or at the very least you will be able to make adjustments to the dough/process which will allow you to move closer to the desired finished crust characteristics.

[Re: Quest for a tender neapolitanish pizza](#) **134**

You have the wrong type of dough docker (metal pins?) The most effective dough docker is the DDCH7755 from American Metalcraft <www.amnow.com>. I'm sure there are others like it but this will give you an idea of what it looks like. Since you have an IR oven set the emitter temperature at 650F for both the top and bottom, if the oven doesn't show emitter temperature set the actual baking temperature at 400F. If the oven has an open chain conveyor, bake on a screen but if it has a woven wire band you can bake directly on the band. Baking time will be a bit longer at about 3-minutes.

[Re: dried out crust after parbaking](#) 135

What you have described is a classical case of dough collapse due to insufficient par-baking. The minimum par-bake time in an air impingement oven will be about 2-minutes at not more than 400F and even then it won't be the best par-bake either. This is because if the oven is profiled to bake pizzas on a raw dough skin, as most are, it has full open fingers across the bottom and a combination of open and partial or even closed fingers across the top which results in the top of the skin receiving less bake than the bottom (that's a similar heat pattern to that which is used to bake pita). Now you know why the skin wants to "pita" during baking. Since I didn't see anything about docking, I'll assume you're not docking the skin. Your best chance to accomplish what you are trying to do is to dock the skin, place it on a pizza screen and bake it at 400F for 2-minutes. You may need to adjust the baking time and temperature slightly but this will get you very close. A difference of 10-seconds in bake time can mean the difference between success and failure....it's that sensitive. Also, immediately upon removing the par-baked crust from the oven turn it upside down for cooling.

[Re: dried out crust after parbaking](#) 136

Here is a good starting dough formula:

Flour: Bread type flour with 12 to 12.8% protein content 100%

Salt: 1.75%

Sugar: 2%

IDY: 0.375% or CY: 1%

Water: 62% (variable)

Oil: 2%

Put water in mixing bowl, add salt and sugar, add flour and yeast on top of the flour. Mix until no dry flour can be seen in the bottom of the bowl, then add the oil and mix an additional minute at low speed, then finish by mixing 8 to 10-minutes at medium speed. Target finished dough temperature is 75 to 80F.

Take directly to the bench for scaling and balling.

Scale and ball entire dough in not more than 20-minutes.

Place dough balls in dough boxes and lightly oil the top of each dough ball.

Cross-stack dough boxes in the cooler until INTERNAL dough ball temperature reaches 50F.

Down-stack and kiss the dough good night.

Allow to CF for a minimum of 24-hours (48-is better).

Remove about a 3-hour supply of dough balls from the cooler and allow to set AT room temperature until the internal dough ball temperature reaches 50F.

Begin opening the dough balls into skins as needed. They will remain good to use for about 3-hours.

Any unused dough balls can be opened and placed on screens and stored in the cooler in a wire tree rack (cover with a plastic bag to prevent drying)

To use these pre-opened skins, remove from cooler 20 to 30-minutes prior to anticipated use time, then REMOVE FROM THE STORAGE SCREEN and place onto your baking platform (screen, disk, pan, etc.), dress and bake as normal.

Note: Pomace grade olive oil is better for use in the dough than EVOO, it's cheaper too!

[Re: Dough recipe for commercial conveyor pizza oven at 550 degrees](#) 137

Also, when checking around, don't forget to look for steel cake pans, they come in both steel and aluminum and are available in a host of different sizes. I've got a few in 8 and 12-inch (square) X 1" deep with a dark green finish (called Bake-Prep) that

work reasonably well.

They went for next to nothing when AIB liquidated its baking facility.

[Re: Metal Proofing Pans vs Plastic Proofing Trays](#) **138**

Check the bags to make sure they all have the same milling lot number. Also, remember that storage can/will affect the flour too. If the flour has been stored for a period of time (slow turn over by your distributor) it will dry out. Flour will typically have about 14% moisture content at the time of milling and bagging but it can dry out to as low as about 10% due to long storage times (+/- 3-months) from the date of milling.

[Re: Can you explain my observations?](#) **139**

Have you looked at the pans from Crown Cookware <www.crowncookware.ca>, they carry a lot of the same type of pans that Allied carried. We had a few of their pans when I was at AIB and they held up as well as those from Allied Metal.

[Re: Metal Proofing Pans vs Plastic Proofing Trays](#) **140**

Use only the unglazed, not the porcelain. When I got mine the size was 14 X 14, 6 X 6 is pretty small. I got mine from an independently owned local tile and carpet store though I recently saw some at our local Habitat for Humanity Restore for next to nothing.

[Re: Are these quarry stones ok to use at home?](#) **1581**

The easiest way to find R.H. is to use two dial/stem type thermometers, using two Styrofoam cups, push on thermometer stem through the sides of one cup and place into the box, the other thermometer is pushed into the other cup (about an inch from the top) so the tip is just touching but not penetrating the opposite side. Wrap a piece of paper towel or absorbent cloth around the stem portion inside the cup, fill the cup with water (to about an inch BELOW the thermometer stem) at the same temperature that the other thermometer is reading.

The thermometer w/o water is the dry bulb and the one with water will be the wet bulb. Begin monitoring after 30-minutes in the box. A 4 to 5F difference in temperature will be indicative of approximately 80% Relative Humidity/R.H. If you go on-line you can down load a relative humidity chart showing the the temperature differential between wet and dry bulb measurements for any desired R.H. at any dry bulb temperature.

[Re: sufficient humidity for dough retarder/proofer?](#) **1582**

In that case, wouldn't it just be a lot easier to grease the pan and place the dough ball(s) onto the pan to ferment? When making focaccia I normally weigh out the dough so I'm working with a single dough ball per focaccia sheet. After about an hour to hour and a half use a tolling pin or pastry pin to partially open the dough ball to somewhat the shape of the pan, cover again and allow to finish fermenting, then hand fit the dough the rest of the way to fit the pan, set aside and allow to proof for 45-minutes, re-stretch the dough to fit the pan if necessary and allow to continue proofing to desired height, dress the focaccia as desired and bake.

Remove focaccia from the baking pan immediately after baking and allow to cool on a wire rack. After cooling they can be placed back into the pan if desired. If you don't remove them from the pan immediately after baking the bottom will become soggy due to condensation.

[Re: Could I let proof my focaccia dough directly on the pan ?](#) **1583**

Why not just put the dough balls into a suitably sized plastic bowl? You are going to

need to remove the fermented dough balls from the pan anyhow to oil/grease the pan. If you grease the pan you can place the dough balls directly onto the pan to ferment then press the dough into the pan by hand. We do something similar to this with deep-dish pizzas and it works well. If you are planning to oil the pan this won't work as the dough will absorb the oil during the fermentation time. You're still going to need to cover the pan to prevent the dough from drying out and forming a crust during the fermentation period.

[Re: Could I let proof my focaccia dough directly on the pan ?1584](#)

What we're talking about here is one way slice operators recon their slices for sale. Heated/humidity controlled box straight to a deck oven for about 1-minute then handed off to the customer. It'll be crispy and have the visuals but it will not have the overall flavor since so many of those flavors are highly volatile and are lost soon after baking, much less cooling.

[Re: Help on modifying the level of browning on a Neapolitan pizza bottom1585](#)

You will experience drying of the dough at anything less than 80% R.H. Constant 80% is what you want.

[Re: sufficient humidity for dough retarder/proofer?1586](#)

The characteristics you're looking for are achieved at very different baking temperatures. You might try baking at 900F+/- to achieve the leaoparding and Neapolitan characteristics, then remove the pizza from the oven to cool for a few minutes, place it back into the oven for a second bake (directly on the deck) and hope this will brown the bottom and provide additional crisp without significant adverse impact upon the top of the pizza. This is similar to the way a store bought frozen pizza is made and handled, have you ever baked one that wasn't crispy? Another approach might be to experiment using a par-baked crust. For this you will want to bake the crust at not more than 450F, cool it, then dress it and give it a final bake at about 650F. Some experimenting will be needed but either method holds some promise.

[Re: Help on modifying the level of browning on a Neapolitan pizza bottom1587](#)

A good RH to shoot for is 80 to 82%. If you get much above this you will get condensation forming with and opening or closing of the door or on anything placed in it that is not at the operating temperature of the box.

[Re: sufficient humidity for dough retarder/proofer?1588](#)

Maybe a New Haven style pizza? Think of it ad a crispy New York style pizza.

[Re: Help on modifying the level of browning on a Neapolitan pizza bottom1589](#)

Most everything you like about the flavor of the 7/11 product will be compromised by traditional canning methods so in my opinion, freezing is the lesser of two evils.

[Re: Is it good practice to jar \(canning\) smaller quantities of 7/11 tomatoes?1590](#)

Maesh;

You came to the right place. Tell us what you have been doing and we'll see what we can do to get you on track to making some great pizzas.

[Re: Two Failed Attempts and Looking to Get Better!1591](#)

The 7/11 Ground Tomatoes with skin is my favorite also, I use it just as it is right from the can or I add fresh basil and garlic to the skin at the time of saucing.

[Re: Wowzer! Stanislaus 7-11 Tomatoes...1592](#)

Matt;

The implication is indeed correct.

[Re: Cold then warm then cold?1593](#)

That's a good height for the boxes. Try using white mineral oil to treat the wood. We use it here in the U.S. all the time to treat out wood bench tops. If you can't find it on line or through a local distributor try asking for it as a local pharmacy, if they don't have it they should be able to get it for you. A pint will go a long ways.

[Re: Upgraded Dough Boxes1594](#)

Beautiful AND Fantastic!

[Re: DIY Pizza workbench1595](#)

I can't tell from the pictures what the dimensions are but also keep in mind that you don't want the boxed to be too big/tall with regard to the size of the dough balls. This is why commercial boxes are made in two basic heights to accommodate large or small dough balls. A box that is too high/tall will have excessive head space which is conducive to drying of the dough balls. Since cross-stacking is desirable when using dough boxes the dough balls are usually lightly oiled after being placed into the box to prevent drying during the cross-stack period so drying of the dough balls is usually not an issue even with a partially filled box.

[Re: Upgraded Dough Boxes1596](#)

Assuming you mean you are going to bake pizzas for 200 to 250 people. Individual pizzas or large pizzas which will be sliced? In so how large? Is your oven a single or a double stack? Over how long of a period of time will you be making the pizzas? Keep in mind that you will only be able to bake 5 to 6 pizzas at a time (depending upon size) with an average baking time of 7 to 8-minutes (at best), so probably figure on about 35 pizzas per hour per deck (that might even be a bit optimistic). If you do a 16-inch pizza (5 per deck) and cut it into four slices you will get about 50-square inches per slice or about the same as a 8-inch individual pizza which should be sufficient for one person. $250 \div 4 = 63$, 16-inch pizzas will be needed. $63 \div 5 = 12.6$ (13) full oven bakes. Assuming an 8-minute bake (?) this means 104-minutes for a single deck or about 52-minutes of baking time for two decks (call it an hour).

Take this with a grain of salt as it's based on a lot of assumptions. Guessing you will need a total of 3 possibly four people to do this.

[Re: Advice please 1597](#)

Try this instead, immediately after mixing (targeted finished dough temperature 75 to 80F) scal and ball the dough, lightly oil the dough balls then straight into the fridge (uncovered for at least 2-hours, then cover) and allow to cold ferment for 48-hours, remove from fridge, allow to warm AT room temperature until the dough balls reach an internal temperature of 50 to 60F, then open into skins, dress to the order and bake, this should address the dough memory issue and improve the crispiness of the finished pizza at the same time.

Tom Lehmann/ The Dough Doctor

[Re: Dough help, still not quite right1598](#)

Matt;

The only problem that I see is that you don't have a clue as to how much actual fermentation the dough is really getting so inconsistency is going to be the name of

the game over time.

[Re: Cold then warm then cold? 1599](#)

Bleaching is done only to remove the beta carotene (yellow) pigments from the flour, it is 100% purely a cosmetic treatment.

As to why the new flour is performing differently I cannot say. You are dealing with two different milling lots and don't forget that we have had very high temperatures lately and there is no way of telling under what conditions the flour has been exposed to or for how long.

[Re: Bleached vs unbleached? 1600](#)

To the best of my knowledge the two main ways to measure flour particle size distribution is either by super sieving or by Micro-Trac Particle Size Analyzer. I worked with the Micro-Trac back in the late 1970's looking at a whole range of flours to see if particle size distribution varied much between the different mills and if particle size distribution had a significant impact upon flour performance characteristics. Surprisingly, we found very little variation in particle size distribution (this is amazing and a testament to the knowledge of the flour millers) between different mills and milling companies for like flour types and when we experimentally milled flours with different particle size ranges the only impact we saw was on both total flour absorption as well as the rate of hydration once water was added to the dough.

I think this is why we usually don't see much research done on particle size.

[Re: Flour Particle size distribution very interesting :\) 1601](#)

Things that may cause a dough ball to flatten during the fermentation period:

- 1) Dough absorption (higher = flatter)
- 2) Amount of gluten development during mixing (more = less flat). To a point, then it's reversed.
- 3) How tightly the dough ball is rounded (tighter = less flat)
- 4) Use of additional enzymes = flatter.
- 5) Finished dough temperature (higher = flatter)
- 6) Temperature of room or fridge (higher = flatter)
- 7) Flour strength (stronger = less flat)
- 8) Failure to cross-stack = flatter.

Those are the high points.

[Re: Dough balls cold ferment 1602](#)

66 to 68% will probably give you the best results at those temps, don't know your dough formula but there should not be any sugar, eggs or milk in it if you are looking for optimum crispiness.

[Re: Hydration Percentage, Baking Time, and Oven Temperature 1603](#)

Without knowing your dough formula and how you're managing it I can't say very much except to maybe try to knead in more flour, then give the dough some bulk fermentation (2-hours?) which will allow time for the newly incorporated flour to hydrate, then ball and allow the dough balls to rest until they can be opened.

[Re: High hydration balling 1604](#)

Lower absorption doughs are slower to expand (oven spring) in a very hot oven so they tend to retain more moisture than higher absorption doughs which expand more freely and as a result exhibit better bake-out resulting in a crispier finished

crust, now, if the crust will RETAIN that crispiness is a totally different matter, one which depends more upon baking time/temperature than dough absorption.

[Re: Hydration Percentage, Baking Time, and Oven Temperature](#) **1605**

I think a better solution might be to experiment with finished dough temperature. Begin incrementally reducing the finished dough temperature to see if you can get improved results. I'm guessing if you can get it down to something in the 60 to 65F range you might get away with it. That still doesn't address a sub-par refrigerator though, but it might allow you to use it for dough storage only.

Desperate times call for desperate measures.

When I was in Quito, Ecuador our cold room (can't call it a cooler or refrigerator) was nothing more than an insulated room packed with frozen meat and seafood for use by the hotel restaurants. No electricity, no nothing! The only way we could hold dough in that room was to make dough as cold as possible, which was right at 60F, using ice and ice water. The longest time we could get from the dough was 48-hours so we were able to make it work for us.

[Re: At what temperature should I be doing a cold ferment?](#) **1606**

When dough is fermented prior to being placed in the fridge two things happen, (1) the dough becomes less dense and a much better insulator which allows the dough to continue fermenting for a significantly longer period of time at a faster rate, this is exacerbated by the development of heat in the dough through heat of metabolism which is continually warming the dough to some extent. (2) The acids and enzymes will continue to work on the gluten to further weaken it during that extended CF period. Why not reverse your order? CF first, then RT ferment? This will help to reduce the acid development so the protein/gluten isn't exposed to the acids for such a long time. Remember, fermentation is much like marinating a tough piece of meat, the right amount is beneficial but too much will give the meat all of the fine mastication properties of a piece of liver.

With this said, I have no way of knowing if you are exceeding the fermentation tolerance of your flour or not. Not all flours will tolerate that kind of fermentation, so you may need to experiment with different fermentation times to find out what is right for your specific flour.

[Re: Reballing..is it hopeless..or am I just doing it wrong?](#) **1607**

Looks great!

Try brushing the skin with melted butter (edge to edge) then sprinkling with a cinnamon-sugar mixture before adding the apple, this turns the crust into something more like a pastry than a pizza crust. I do this with my dessert pizzas and it adds a whole different dimension to the flavor.

[Re: Apple Pizza Desert I serve in my restaurant](#) **1608**

36 to 38F is an excellent temperature to operate a walk-in, reach-in or home refrigerator at.

[Re: At what temperature should I be doing a cold ferment?](#) **1609**

No two lots of flour are made from the same grist (blend of wheats) so it is up to the flour miller to do his/her magic to produce a finished product with the consistency we have come to expect. This is why so much testing is done on wheat and flour as it provides the tools/information needed by the flour miller to develop a grist to meet the specific needs of the flour being milled. Even with all of the data available and "magic" performed, things still go awry once in a while, and if that's not enough, with imported flour the conditions under which the flour is held during

shipment may not always be the most conducive to maintaining the quality of the flour. Even domestic flour is highly subject to unfavorable storage conditions during distribution, so despite the best efforts, flour is still possibly the single most variable ingredient we work with. This is why in commercial applications the bulk flour delivery is always accompanied with a Farinograph report of the flour which shows flour absorption, mixing time, and strength characteristics for that specific lot/shipment of flour, using the Farinograph report the production facility will then make the necessary changes to their processing of the dough to maintain a consistent quality dough.

Flour is variable, especially when it comes to absorption, you may not always see it at home but it is still there, sometimes though it is more evident than at other times for any number of reasons.

[Re: Inconsistencies in hydration between sacks of flour](#) **1610**

RETURN IT! 40F is the absolute HIGHEST temperature that you should be holding any refrigerated food at and once you open the door or put anything into it 40F is just a passing memory.

[Re: At what temperature should I be doing a cold ferment?](#) **1611**

Yes, if it's placed in the fridge right after mixing, scaling and balling.

[Re: Dough balls cold ferment](#) **1612**

Here's a list of things that will help:

Finished dough temperature: 75 to 80F (favoring 75F).

Tightly round/ball the dough.

Lightly oil the dough balls, not the inside of the box. Best is to place dough balls into unoiled box and then lightly wipe the top of the do balls with oil. This will prevent the dough balls from skating around in the box.

Leave the dough box uncovered for at least 2-hours (preferably until the internal dough ball temperature reaches 45F) then apply the lid.

These simple steps should effectively address the problem you're experiencing.

[Re: Dough balls cold ferment](#) **1613**

Richard;

I think your problems stem from two issues, one is due to the fact that you are tightly lidding the fermentation container right away upon placing it in the fridge, instead do this, lightly oil the dough ball when you place it into the container, then leave it UNCOVERED for at least 2-hours before applying the lid. If you use a snap on lid be sure to make a couple pressure release cuts/holes in the lid, a much better option is to use a loosely fitting cover, like a piece of aluminum foil.

Secondly, I don't think you're mixing your dough long enough, it needs to be mixed just until the dough takes on a smooth, satiny appearance. What is the finished dough temperature? You should be looking for something in the 75 to 80F range.

[Re: Dough wet and sticky after 24 hour cold ferment](#) **1614**

Huh? I just Googled it again and it gave me the entire process step by step including temperatures, no I'm not a member either.

Google: AACC ash measurement procedure for flour.

[Re: how to get the ash content from self milled flour?](#) **1615**

It sounds like the dough just needs more fermentation when it's made with that specific flour. It that's out of the question you can also increase the finished dough temperature to something in the 84 to 86F range, that will provide more

fermentation to the dough within the same time period.

[Re: Rogers nothing added flour for Canadians](#) **1616**

May I ask why you want to measure the ash content of your flour? The ash content has little, if any, impact on flour performance. It does impact the color of the finished crumb (not a big deal with pizza), it is used mostly to provide some measure of flour extraction as well as a quasi measure of flour quality as it relates to protein content. By this I mean that you can have two flours with the same protein content but different ash contents, as a rule the flour with the lower ash content will be the stronger of the two, that's about where the usefulness of ash content ends. In the U.S. a typical patent grade flour made with a 78% extraction will have about 0.54% ash content while whole wheat flour will go about 1% or a bit more.

If you want to accurately measure the ash content of the flour Google "AACC Approved Methods" and you will find the approved method for determining the ash content of flour.

[Re: how to get the ash content from self milled flour?](#) **1617**

Breaking the dough down into the smallest size pieces possible will be the best way to handle the dough, this means scaling it into desired weight pieces, and form into balls, lightly oil each dough ball and place into individual plastic food bags (like bread bags) DO NOT use Zip-Lock bags. Pull the bag snug to the dough ball, twist the open end into a pony tail and tuck the pony tail under the dough ball as you place it into the fridge. To use the dough you will need to remove it from the fridge about 90-minutes prior to use, roll the bag down around the dough ball and invert it over a floured surface, flour the entire dough ball and begin opening into a skin by your preferred method.

[Re: Dough Storage](#) **1618**

Probably at least 4-hours.

[Re: Pizza dough, fridge bulk ferment](#) **1619**

Probably not as there will probably not be sufficient time for the dough balls to sufficiently relax for opening into skins, a much better approach would be to mix the dough, take immediately to the bench for scaling and balling, lightly oil each dough ball and place into individual plastic bags, twist the open end of the bag into a pony tail and tuck in under the dough ball as you place it into the fridge. To use the dough ball(s) remove from fridge about 90-minutes prior to the time when you want to open them into skins, roll the bag down around the dough ball and invert over a floured surface allowing the dough ball to fall from the bag into the flour, flour both sides of the dough ball and open into a skin in your normal manner.

[Re: Pizza dough, fridge bulk ferment](#) **1620**

After cleaning out your skivvies the real fun begins with cleaning the mess outta the microwave. :-D

[Re: I just exploded a stick of butter in the microwave](#) **1621**

QJ;

Your "funny thing" observation might be giving us some insight into the problem, as the dough is warmer with the molasses/oatmeal bread and you don't have the keyholing problem this would lend credence to the fact that we are probably on the right track with increasing the finished dough temperature. This just underscores why it is important to always monitor finished dough temperature and in the case

of bread making, target the same finished dough temperature, regardless of the type of bread being made.

[**Re: Bread question for Tom1622**](#)

If I understand you correctly you make the "dough" in the afternoon, divide into 30.8-ounce pieces and cold ferment the dough pieces overnight, in the morning you remove it from the fridge at 6:00 a.m. and allow the dough to rise (no sure how much it's going to rise as it just came out of the fridge) and then at 7:45 a.m. you mould and pan the dough, allow it to final proof for 75-minutes, then bake at 350F for 35 to 40-minutes. If this is correct the dough does not receive sufficient fermentation time (typically 3 to 5-hours at room temperature for pan style loaf breads). Pan breads react very differently to yeast level than pizza doughs, as you can almost walk the volume/height of the bread up or down using adjustments in the yeast level. An increase in yeast level will only result in more dough expansion (oven spring) which will only further exacerbate the problem. Instead, try increasing the finished dough temperature which will allow the dough to ferment longer and faster in the fridge. I would suggest going up in 5F increments. Let's see if that will effectively address the problem. One other thing, just to confirm, your pans ARE dark colored, right? I also suggest looking for a finished internal loaf temperature of a little over 200F (193F is really not sufficient for what you are doing). I don't know your dough formula but the loaves look to be a bit light in color (camera or actuality?), you can develop a stronger side wall on your loaves by using sufficient sugar in the formula to achieve a nice brown/mahogany colored top and side wall.

[**Re: Bread question for Tom1623**](#)

QJ;

By the way, the official name for that fault is "keyholing", if you cut a slice from the loaf it will look like an old fashion keyhole.

[**Re: Bread question for Tom1624**](#)

QJ;

That's an easy one to answer, Assuming you're removing the loaves from the pan immediately upon removal from the oven and the loaves are sufficiently baked (at least 20-minutes for a 1-pound loaf) insufficient dough fermentation is the answer. I've seen it happen hundreds, if not thousands of times over my years in running the Baking Research Lab at AIB.

[**Re: Bread question for Tom1625**](#)

2% IDY with extended room temperature fermentation time would be considered outrageous. That amount of yeast would probably metabolize all available sugar in 6 to 10-hours.

[**Re: Volume vs Fermentation1626**](#)

Your mixing attachment, looks like it should do the job, just watch the dough during mixing, you do not want to see the dough grabbing onto the attachment and going for a ride around the inside of the mixing bowl, if it does you will need to mix at a higher/faster speed. If the mixer complains when you do that you will need to down size your dough so as not to over load the mixer.

[**Re: Help me with making dough1627**](#)

No, it just takes more time to achieve the same level of fermentation when using a smaller amount of yeast. This is why we use a higher yeast percentage when

making a no-time/emergency dough than we do when making a 5-day cold fermented dough.

[**Re: Volume vs Fermentation**](#)**1628**

Your dough looks to be extremely under mixed. This could be the result of a "J" hook on your mixer as opposed to a reverse spiral dough arm, can you show a picture of your dough mixing attachment? Then too it might be due to mixing a very small dough size where the mixing action is quite poor. It can also result from mixing at too low of a speed, generally 1st/low speed just doesn't cut it as you need to do the bulk of mixing at a higher speed. A correctly mixed dough should come out of the mixing bowl looking smooth. If you go to my web site

<www.doughdoctor.com> I have a series of videos posted and in one of those videos I show how to stage the ingredients in the mixing bowl and mix the dough to the proper consistency. While the video is made using a commercial size mixer you can achieve the same characteristics using a smaller size mixer too.

[**Re: Help me with making dough**](#)**1629**

By allowing the dough to proof for a longer time in the pan immediately prior to baking will impart a more open, porous crumb structure to the finished crust.

[**Re: Final proof time for pan pizzas \(working on Roman al taglio\)**](#)**1630**

The issue is not protease enzymes but instead amylase enzymes which convert starches into sugars. Flours with unusually high levels of damaged starch will exhibit a fairly high initial absorption since damaged starch readily absorbs water (native/intact starch does not readily absorb water), then as the dough begins to ferment the enzymes contained with the yeast hydrolyze the damaged starch very fast, releasing the water it absorbed in the process, hence a "gooey" dough.

This could potentially be compounded if the wheat from which the flour was milled had a low Falling Number value (under 200).

There are some countries where the flour is milled on purpose to achieve a higher than normal level of damaged starch as it allows for the addition of more water to the dough BUT it also limits total fermentation time to something like 60 to 75-minutes.

[**Re: Hydration - How low can I go?**](#)**1631**

JPB;

It's simple math, each yeast cell metabolizes sugars during the process which we call "fermentation" as a byproduct each cell produces acids, alcohol, and carbon dioxide plus a small amount of heat resulting from the heat of metabolism. It is primarily the carbon dioxide that is responsible for the increase in volume/decrease in density of the dough during the fermentation period so the more yeast cells you have doing this the more carbon dioxide is being produced within any given period of time and the dough becomes greater in volume. Because commercial yeast is somewhat standardized, meaning if you add "X" amount of yeast, within a given period of time you will get a specific amount of fermentation taking place and if you add "2X" amount of yeast you will (with fairly good predictability) get twice the amount of fermentation taking place (assuming there is sufficient nutrient to feed all of the yeast). With a sourdough you have a bacterial culture which can exhibit a different growth rate than yeast and add to that you have no idea of the concentration so it's no wonder that you will see a different change in dough volume, you're sorta comparing apples and watermelons from a microbiology point of view.

All things equal, less yeast means less fermentation (less effects of fermentation on

the dough and flour) so a dough made with less yeast will show more signs of under fermentation than a dough made with more yeast at any given point of time. This is not to say that doughs made with smaller yeast levels will always show signs of under fermentation, they will just need more time to ferment the dough to the same magnitude that a greater yeast level did in a shorter time. The characteristics of the finished crust will reflect the amount of fermentation the dough received.

[Re: Volume vs Fermentation](#) **1632**

You may call me anything you want, just don't call me late for dinner, especially if pizza is being served. :-D

The only thing you need to do is to pull the twisted end tighter under the dough ball, you want to have the bag nice and snug around the dough ball.

[Re: "Gooey" dough issue \(after baking\)](#) **1633**

It sounds a lot like a high starch damage flour. Try making a dough, immediately scaling and balling after mixing and open the dough after 60-minutes, let me know if the dough handles OK, allow another dough ball to ferment for 2.5-hours to see if it goes all slimy on you.

[Re: Hydration - How low can I go?](#) **1634**

If I might offer a suggestion; reduce the amounts of olive oil and ADY by 50% which will bring them more into line with what is typically used for the dough management procedure it appears that you are using. Also, adjust the water temperature to give you a finished dough temperature in the 75 to 80F range which means you will most likely want to start with 65F water and make further adjustments with following doughs if necessary.

[Re: First batch of dough with the NutriMill](#) **1635**

If your oven heats from the bottom move the stone to a lower rack position, if it has a broiler you can also turn on the broiler while moving the stone to a lower rack position, my guess is that your stone isn't retaining sufficient latent heat so it needs to be closer to the bottom heat source. The other option is to get a thicker stone.

[Re: Having trouble with the bottom of the crust](#) **1636**

Either one works OK, the carbon dioxide generated by the yeast as it ferments will help to provide a protective blanket over the surface of the dough to further prevent drying. However, "loosely" is a pretty subjective term, my definition could be defined as a piece of foil placed over the container with the overlapping edges pulled down but not crimped or fastened to the fermentation vessel/container. In this case you will still need to allow the container to remain uncovered for 2-hours or more before applying the loose fitting lid, if not you will find condensation forming on the underside of the lid.

[Re: Help me with making dough](#) **1637**

Where is the stone positioned in the oven and what is the thickness of the stone?

[Re: Having trouble with the bottom of the crust](#) **1638**

The length of proof time will depend on a number of things such as dough temperature, amount of yeast used in the dough, amount of salt used in the dough, room temperature, dough absorption and to some extent the use of fat in the dough as well as the total dough absorption and flour strength. My advice has always been to proof the dough in the pan sufficiently to give you the desired volume/height and crumb structure characteristics that you are looking for. In most

cases this time will fall somewhere between 45 and 75-minutes, but in some pizzerias where the dough will be placed in the cooler for storage for use later in the day the final proofing time can be as short as 20 or 30-minutes outside of the cooler, but keep in mind that the dough will continue to proof, to a more limited extent, in the cooler so in reality the final proof time is longer than 20 or 30-minutes.

[Re: Final proof time for pan pizzas \(working on Roman al taglio\)1639](#)

I can't say that I've ever made a "trash" pizza for practice. Instead, I've always tried to make a decent pizza, with whatever I've had on hand. This way it becomes an effective learning process. You can use the house brand tomatoes as well as the house brand mozzarella cheese but always strive to make the best pizza you can, even if you're just practicing opening the dough ball into a pizza skin, make the best you can, you will be rewarded for it as your other skills will improve at the same time and you will expand your horizons for making pizza with different ingredients and learning how to cope with different quality ingredients, you might be surprised at how good a pizza you can make using "no name" canned tomatoes and "no name" mozzarella cheese. Just about anybody good pizza maker can make a decent pizza using the "best" ingredients (whatever those might be) but it takes a master to do it using common, no name ingredients.

Just the opinion of someone who's been there and done that.

[Re: Dough,Dough, Dough1640](#)

To be honest with you, there is absolutely nothing wrong with using a 12%/12%+ protein content flour to make your pizzas. My go to flour has, on average, 12.2% protein content and I use it to make most of my pizzas.

[Re: Help me with making dough1641](#)

At 14mm I think the steel will give better results than the unglazed tile.

[Re: Help me with making dough1642](#)

When using individual containers like this just remember to lightly oil the dough balls and leave the lids off of the containers until the dough reaches an internal temperature in the 45 to 50F/7.2 to 9.9C range. If you lid the containers right away you will get significant condensation forming in the containers. There have been some recent posts on this very topic. If you don't want to go to the trouble of lidding the dough balls sometime after they have been put into the fridge you can use individual plastic bags for storing the dough balls, with this method all you need to do is to lightly oil the dough ball, drop it into a bag (like a bread bag), twist the open end into a pony tail to close and tuck it under the dough ball as you place it into the fridge, no need to come back to it until you are getting ready to make your pizzas. To use the dough ball just remove from the fridge about 90-minutes prior to opening (exact time is determined by the length of time needed for the dough ball to warm to 50 to 60F/9.9 to 15.5C, then just roll the bag down around the dough ball and invert the bag allowing the dough ball to fall from the bag onto a floured surface, flour the dough ball and begin opening it into a skin by your preferred method. The bags can be reused several times if desired. A number of posters here use this method as do I. It works very well for all but the very high absorption doughs.

[Re: Individual proofing boxes from Ikea1643](#)

How thick are they?

[Re: Help me with making dough1644](#)

Tomatoes are an acid fruit to begin with, if they are commercially canned citric acid is added to further acidify them to help retain their color and as a food safety measure. Unless it's strictly a flavor thing for some varieties of low acid tomatoes, I don't know why cider vinegar or lemon juice (citric acid) would be added to the sauce. At least with the tomato varieties we work with here in the U.S. (both canned and fresh) if there is a frequent complaint about the sauce it might be that it is too acid, so aside from a flavor thing I'm at a loss as to why additional acid would be added (assuming the sauce is not going to be canned).

[Re: Vinegar or lemon in sauce](#) **1645**

I think with a little more practice at opening the dough balls into skins you will be very happy with the results. Try this to see if it will work for you, use a rolling pin or pastry pin to open the dough ball to about 2 to 3-inches smaller than the desired finished diameter, then finish opening the dough by hand to the full diameter. We used this method to train those who were challenged in ability to open the dough into a skin. By partially opening the dough using a pin you get as much more uniform thickness across the entire diameter, once you get the hang of it you will gravitate away from the pin altogether.

[Re: "Gooey" dough issue \(after baking\)](#) **1646**

No need to tie a knot in the bag to close it, just twist the open end into a pony tail and tuck it under the dough ball as you place it into the fridge.

[Re: Thin Style Pizza](#) **1647**

Note:

In the excellent post by Rolls he recommended a pizza screen in his equipment list, just make sure you season the pizza screen before using it or the screen and pizza will be "as one" after baking. To season the screen just wipe it down with oil and place it into an oven at not over 400F for about 20-minutes, remove it from the oven and repeat the process again. The screen has now been seasoned and is ready for baking. DO NOT wash your screens, instead, just wipe them down with a clean towel, if you get crud on it just allow it to bake off. As you continue to use the screen the seasoning will continue to darken to a black color, this is normal and desirable. Note that once a screen has been properly seasoned it does not need to be oiled for any future use.

[Re: Help me with making dough](#) **1648**

Ditch the Zip-Lock bags and plate, instead go with plastic Food Bags, or in a pinch plastic shopping bags will work OK, lightly oil the dough ball and drop it into the bag, pull the bag down around the dough ball and twist it to close, tuck the twisted pony tail under the dough ball as you place it into the fridge, to use the dough ball just remove from the fridge about 90-minutes prior to the time you want to use it (you are looking for an internal dough ball temperature between 50 and 60F when you open it), turn the dough ball out of the bag onto a floured surface, make sure the entire dough ball is well floured and you're ready to begin opening it into a skin.

My advice is to forget about using the beer for now until you've mastered your first few pizzas, then begin by replacing 50% of the water with a lager beer, master that and increase to your liking.

By the way, adding oil to the dough will not do much for the crust color, you need to add sugar, milk or eggs for that, use sugar for now.

[Re: "Gooey" dough issue \(after baking\)](#) **1649**

While softened water does contain some sodium it is not sufficient to impact the dough with regards to salt level, additionally, soft water tends to make for a softer dough with slightly less absorption capacity. The best water to use when making dough is just plain old hard water. We have discussed the effects of hard and soft water in previous posts.

[Re: "Gooey" dough issue \(after baking\) 1650](#)

Brent;

That's ascorbic acid, not citric acid. The AA is most likely encapsulated to provide a slower reaction as AA uncoated reacts in the mixing bowl. The enzymes which would be appropriate for use in a bread improver are most likely oxidative enzymes which function in a similar manner to low levels of potassium bromate. The rest appears to be nothing more than enriched wheat flour used as a filler/diluent. In short, it appears that you may have taken the nothing added flour and turned it into a regular bread type flour by adding the improver.

[Re: Rogers nothing added flour for Canadians 1651](#)

OMG! I agree with the others on the malt, 4% is WAY TOO MUCH for any kind of diastatic malt, and add an extra "WAY" if the flour you're using is already malted. Your dough fermentation rate must be crazy fast too with 1% IDY and only 1% salt. I would suggest reducing the amount of IDY to not more than 0.5% (half of the amount you're presently using) and increasing the salt to something in the 1.75 to 2.5% range. At 1% salt the crust will typically have what is referred to as a "starchy" taste.

Note: A typical characteristic to excessive diastatic malt is an excessively soft, sticky, gummy crumb structure, when you bite into the crust it will stick to your teeth, sound familiar?

[Re: "Gooey" dough issue \(after baking\) 1652](#)

Without knowing your dough formula and management procedure I can't comment on the dough absorption, but if you're having difficulty handling the dough you might want to back the absorption down by 5% and as you become more proficient then begin increasing the absorption gradually, remember, ever dough has its own sweet spot when it comes to absorption, it is not one of those "one size fits all" type of things and when you add in the proficiency factor you add a whole different dimension to the dough absorption.

[Re: First Pizza 1653](#)

The thing that you do want to watch is the finished dough temperature which can change (increase) on warmer days unless you're in an air conditioned environment, but then you wouldn't be concerned over the humidity. As a general rule, 70 to 75F is a good targeted finished dough temperature but your specific method of dough management might call for something different, point is, just strive to keep it constant by adjusting the water temperature as necessary.

[Re: Hydration on very humid days 1654](#)

Harvest King like "00" flour? No way! They are two entirely different flours milled from very different types of wheat.

[Re: Baking pizza at high altitude 1655](#)

When it comes to air impingement ovens Lincoln, XLT, and all others except Middleby Marshall you can buy most of the electronics from the industrial supplier

McMaster Carr.

[**Re: Oven Parts**](#)**1656**

From the looks of your first pictures it looks like there is a lot of residual dusting flour on the baked crust which might explain the dry mouthfeel. Two minutes probably isn't sufficient mixing, which would result in a tacky dough requiring more dusting flour and the dusting flour is more likely to adhere to the tacky dough, try going for 6-minutes on your next dough, then go for 8-minutes, go directly from mixer to bench for scaling and balling, then lightly oil the dough balls, and plastic bag them (don't use Zip-Lock bags), hopefully the 0.9% yeast is CY, but if by chance it's IDY reduce the amount to 0.4% or if ADY use 0.5%. Allow the dough to cold ferment for 48-hours, then remove from the fridge and allow to warm to 50 to 60F before opening it into a skin for immediate use.

[**Re: Getting closer !!!**](#)**1657**

I've baked pizzas at elevations from San Diego, California to Quito, Ecuador and everything in between, including Denver, Colorado. The fact that the water will boil off sooner at high elevations only results in a drier finished product. To prevent this we typically bake at a higher temperature providing a shorter bake time thus conserving moisture in the product. The reduced atmospheric pressure at the higher elevations will increase oven spring and bake volume (sometimes rather significantly depending upon altitude) which helps with getting a thorough bake with the reduced bake time. This is easily addressed by adjusting the yeast level to give the same volume as achieved at sea level (if that's what we're looking for). Just out of curiosity, have you checked the color of the gas flame to make sure you have sufficient oxygen? I've seen this problem at high altitude a number of times over the years and if the gas fuel mixture is not correctly balanced the oven will still operate but not as efficiently.

[**Re: Baking pizza at high altitude**](#)**1658**

Jr07;

If you tell us what type of pizza you are making and provide a copy of your dough formula and dough management procedure we might be able to provide you with some helpful suggestions.

[**Re: How to make dough more relaxed**](#)**1659**

It's just a matter of preference as to whether one uses a poolish or not but if one is mixing their dough by hand a poolish makes the mixing process a bit easier.

[**Re: Napoletana Pizza Dough with a Poolish**](#)**1660**

If it's just the outer crust/rim that you want more color on egg wash will work as will milk wash or even just painting it with olive oil.

[**Re: What can I add to dough for good browning of pie**](#)**1661**

Just don't over work it when you're rolling it out, I think it'll be fine.
Let us know how it turns out.

[**Re: 48 hour room temperature proof...bad or not?**](#)**1662**

When we reference "ambient" temperature as it pertains to dough storage we are typically referring to temperatures in the 70 to 85F range. But when asking what is the ambient room temperature? It is what it is.

[**Re: bulk retard vs ball retard**](#)**1663**

Are you following the current posts on this very topic?

[Re: Browning "white" neapolitan pizza](#) **1664**

To address your question regarding acidity and crust color development, during fermentation three main acids are produced, acetic, lactic and propionic, this is why the pH of the dough and also the finished crust is decreased with longer fermentation times or conditions resulting in a greater amount of fermentation. It is well recognized that lower pH environments have an inhibiting effect upon crust color development, this explains why sourdough breads have such a light crust color. Conversely, a higher pH will promote more crust color development, but before you run off and start thinking about adding soda to the dough remember that yeast is an acid loving micro organism so it fares much better in an acidic environment than it would in an alkali environment (this is why yeast fermentation produces acids as a byproduct, to improve its environment for its own survival), all micro organisms pretty well operate this way, producing byproducts conducive only to their own survival. If you were to add soda to the dough to enhance crust color the yeast would ferment very sluggishly, if at all, depending upon the amount of soda added, and the finished crust flavor would not be something you would be drooling over.

[Re: Too much leoparding but very white crust](#) **1665**

Here is how you remove those dents from the bowl.

Materials needed:

A bag or two of fine sand

Make a square wood frame about 5 to 6-inches high and about 18-inches square.

What to do:

Pour the sand into the wood frame.

Wet the sand (to about the consistence needed as if you were building a sand castle).

Place the bowl into the sand so the dent you are removing is at the 6 o-clock position.

Push the bowl down firmly to nestle the bowl into the sand.

Using an auto body hammer with a convex face carefully begin working the dent out starting at the edges of the dent and going around it working towards the center. If you don't have or can't borrow an auto body hammer use a carpenter's claw hammer (it has a convex face). Go slow, use many taps from the hammer and the dent will be worked out. The reason for using the wet sand is because it provides support for the surrounding metal so all that is worked out is the dent. Repeat this for each dent. I used to repair dented bowls for our A-200 mixers at AIB this way and they came out just fine.

NOTE: DO NOT USE A BALL PEEN HAMMER.

After you get the bowl "de-dented" let me know if you need help adjusting the bowl clearance.

[Re: Hobart A 200 restauration](#) **1666**

I don't have a "recipe" but I do have a dough "formula" in bakers percent.

Sponge:

Flour: 60%

Water: 50% (based on the weight of the sponge flour)

Yeast: 0.25% (based on the weight of the sponge flour)

Set Temperature: 70F/21C

Allow to ferment 18 to 24-hours at room temperature.

Dough:

Flour: 40%

Salt: 2%

Sugar: 2% (optional/don't know what type of pizza you are wanting to make)

Water: 60% +/- (based on TOTAL flour minus what was added to the sponge)

Note: Yeast percentage is based on CY (compressed yeast).

[Re: Introduction - Stiff starter](#) **1667**

Sallam;

Less dense = lighter in weight for a given volume.

Better insulator = resists temperature change.

Resistant to temperature change = more difficult to change the temperature.

In all probability, room temperature fermentation is going to be the best when using a sourdough starter.

[Re: bulk retard vs ball retard](#) **1668**

Maybe it's just the angle of the picture but it looks more like an A-120 (12-quart) mixer. In any case you will want to replace the useless "J" hook and get a reverse spiral dough arm for your mixer, you'll be glad you did after trying to mix your first dough. That was a really great find, you've got most of the attachments (all of the most commonly used ones) with it too. Good Deal!

Be sure to bolt it down to the table you mount it on, we've had more than one take a walk off of the bench at AIB (not a pretty sight). If the bowl is rusted you can have it tin plated to restore it to "like new".

If there are any dents in the bowl, pretty common) let me know and I'll ll let you know how to remove them (do NOT go beating away at them with a hammer!). When you get a reverse spiral dough arm you will want to check and probably reset the clearance between the bottom of the dough arm and the bowl, it makes a big difference in how the doughs mix.

[Re: Hobart A 200 restauration](#) **1669**

Additionally, I think it's the increase in acidity of the dough that is preventing the crust from developing more color. If you make a pizza from the dough at 24-hours and the crust develops better color this would give validity to that premise.

[Re: Too much leoparding but very white crust](#) **1670**

Try these:

www.Fourstarfarms.com

www.maineatmosphere.com

[Re: Flour Source in Eastern MA](#) **1671**

You can add sugar to the dough formula about 3% should be right. You can also replace 50% (1/2) of the water with whole milk. Be sure to scald the milk first, then allow it to cool in the fridge for a few hours before using it. Either of these should improve the color of your finished crust.

[Re: What can I add to dough for good browning of pie](#) **1672**

Mixing time is the same regardless of how long you plan to CF the dough. Mix the dough JUST until it takes on a smooth appearance, more than that is not necessary or desirable.

[Re: Mixing Time](#) **1673**

It really doesn't work that way, pick one, cold fermentation or room temperature fermentation and go with it. After the dough has cold fermented it will be significantly less dense making it a better insulator and more resistant to temperature change so it will be just all that much more difficult to manage, even in ball form. Another question is, how does your sourdough starter perform under refrigerated conditions? Some starters go all but dormant at refrigerated temperatures so placing the dough in the fridge would be an exercise in futility as not much will happen. Additionally, my comments on a dough made using refrigerated dough management v/s room temperature dough management was based on the use of yeast, not a sourdough starter. The use of a sourdough starter will essentially wipe out any perception of flavor change as it will dominate the flavor profile.

[Re: bulk retard vs ball retard](#) **1674**

Being a home pizza maker I will "assume" you are working with smaller size doughs, less than 1Kg. in total weight? Please confirm or tell me what your total dough weight is.

[Re: bulk retard vs ball retard](#) **1675**

Your starter is comprised of various yeast and bacteria strains, refrigerated temperatures will dramatically slow but not stop the growth rate of both, however some bacteria are more adaptive than others and will adapt to the cooler temperature and thrive thus taking over the medium and becoming the dominant strain (this is how sours are "lost").

[Re: What we have here...](#) **1676**

Yes it does, hard, potable, tap water is the best just do long as it isn't sulfur water. Distilled and soft water are not recommended as they result in a softer, slightly weaker dough condition.

[Re: Water](#) **1677**

It also helps to reduce the amount of dusting flour picked up by the dough during the opening process, and because I open my dough by bench stretching the dough slides much easier on the bench top when the top (smooth) side is placed down.

[Re: Dough ball, which side is the bottom?](#) **1678**

We just recently quite a bit of discussion on this very topic, if you check back a week or two you should be able to find it.

Pizzerias (box chains) use a refrigerated dough ball method of dough management because it allows them to use the dough over a several day period and it provides much better consistency than room temperature/ambient fermented doughs. As a home pizza maker you will most likely be using all of the dough that you make at one time so room temperature/ambient temperature dough management is a viable way to manage the dough, however you will need to modify the dough formula by using less yeast and paying special attention to the finished dough temperature (70 to 75F) failure to do so can end up resulting in over fermented dough. Oven spring will be about the same for both methods of dough management, as for flavor, it's hard to describe as it's pretty subtle, but room temperature/ambient fermentation provides a finished flavor similar to that of white pan bread (U.S. and U.K.) while cold fermentation provides a more complex flavor without the acidity common to crusts made from room temperature/ambient temperature managed doughs.

[Re: bulk retard vs ball retard](#) **1679**

I always orient the dough ball so the top of the dough ball becomes the bottom of the skin.

[Re: Dough ball, which side is the bottom?](#) **1680**

Sure, you will need to make an emergency dough.

Double the amount of yeast.

Replace 2% of the water with vinegar.

Reduce the amount of sugar in the dough by 50%.

Adjust the dough water temperature to give you a finished dough temperature of 85 to 90F. (about 80F water temperature +/-)

From that point on process as directed but do not CF, instead just bag the dough balls and place on the counter top to ferment for 2-hours, then turn out of the bag onto a flour dusted surface, and open into a skin for immediate use. Don't go expecting much in terms of flavor or "digestibility" and you won't be disappointed. If you want to learn more about Emergency Doughs go back in the archives as we've had quite a bit of discussion on the topic.

[Re: What am I doing wrong???](#) **.....1681**

Rolls;

You are correct, we developed that test when we had our AIB Pizza Seminars and it works very well, but there is one problem with it, it is almost impossible to accurately describe how to do it much less interpret the results as your thumbs are pulling apart. I'm planning to do a new pizza video series with PMQ later next month and that is going to be one of the things that I'll be demonstrating, once seen it is easy to understand and do.

[Re: Mixing Time](#) **1682**

Absolutely correct, the milk will provide lactose sugar which readily browns during baking (the sucrose will not brown during baking unless yeast is present to invert it into reducing sugars). Eggs will also contribute to the browning process, but if you want more color just add some dextrose/corn sugar and you will get all the crust color you want.

[Re: Type of flour for scones?](#) **1683**

All commercial wheat varieties, world wide, in use today are hybrid varieties, so much so that they are not even named anymore (not since the 1970's) they are just designated by number sequences. If you want to play with a certified pure variety search for Turkey Red wheat, it is still grown, mostly in N.W. Kansas, and available on a limited basis. You might be able to find some on the Internet. Once you find it you will need to mill it into flour. I'm not aware of anyone selling Turkey Red flour. If you want to make the crust more digestible, think fermentation.

[Re: New home pizza maker with too much to learn](#) **1684**

Additionally, I'm betting that your finished dough temperature is too hot (as indicated by the use of "lukewarm water" as opposed to cool/cold water) A dough that is too hot will experience excessive fermentation (further compounded by the use of 1.7% ADY which is way too high, a better level would be 0.5%) which will result in the yeast consuming all of the available sugars with little or nothing left for browning plus a byproduct of fermentation is acid which will also inhibit crust color development so the excessive fermentation is serving you a double whammy. With only 1.3% salt I'm also betting that the finished crust leaves a bit to be

desired in the flavor department, the crust might even taste "starchy" which is an indication of insufficient salt. Since salt also regulates the fermentation rate it is further compounding the excessive fermentation issue cited above, sometimes ya feel like you just cant win.

I can't comment on the malt powder that you're using as I don't know the L (Lintner) value of it. I always use a 20L malt powder at 0.25% when I'm working with an unmalted flour. As for mixing the dough, just mix it until it takes on a smooth appearance. Use just a small amount of the water at 100F to suspend and activate the ADY in and adjust the temperature of the remainder of the water to 60F. Be sure to add the cold water and the yeast suspension to the bowl first, then add the flour, malt powder and salt and sugar if you are using it last, then begin mixing. Mix just long enough to achieve a smooth dough appearance. Measure the finished dough temperature, you are looking for a temperature in the 70 to 75F range. Immediately scale and ball the dough, wipe the dough balls with a little oil and place into individual plastic bread bags (not ZIP-LOCK), twist the open end into a pony tail and tuck it under the dough ball as you place it into the fridge to ferment overnight. When you're ready to use the dough on the following day remove the dough balls from the fridge about 90-minutes before you plan on opening them into skins, once opened, dress and bake immediately.

I think this will get you started to making a much better pizza. Keep us posted on your results.

[Re: What am I doing wrong???](#).....**1685**

In one word: ABSOLUTELY. There are just so many variables at play when it comes to mixing time that providing an approximate mixing time is like trying to predict the weather. The mixing attachment type and speed, the type of mixer, size of the bowl, size of the dough, dough absorption, flour characteristics, dough formulation, even the surface texture of the bowl comes into play. Don't worry about the time, instead mix the dough JUST until it takes on a smooth appearance and then adjust the water temperature to give you the targeted finished dough temperature

[Re: Mixing Time](#)**1686**

When the dough is bulk fermented prior to CF there is no way I can say how long you will need to CF the dough balls as I have no idea of how much fermentation the bulk dough has already received.

We just recently discussed bulk fermentation and ball fermentation, for many home pizza makers there isn't any difference if you bulk ferment or ball ferment because of the minor difference in dough size. Due to the higher ambient temperature room temperature/ambient fermented dough formulas will contain less yeast than CF dough formulas.

With regard to allowing your dough balls ferment at room temperature (25C/77F) the answer is: only until they can be easily opened into skins.

With regard to allowing the dough balls ferment at 18C/64F) the answer is the same.

[Re: How should the dough after bulk look like ?](#)**1687**

It's just added as you would any other dry ingredient, I've always added it right on top of the flour.

[Re: Found NY style Pizza in Vegas. But, how to make dough without NYC water/flour?](#)**1688**

N.Y. style pizza is made with the highest protein flour commercially available because it provides the desired finished crust characteristics, namely chew and

foldability which allows the slice to be folded for consumption on the run. Soft water is easily addressed by the addition of 0.25% calcium sulfate to the dough, or you can "bite the bullet" and just reduce the dough absorption slightly to compensate for the slightly softer dough resulting from the use of soft water as compared to hard water. This has been discussed here at great length and I've also written a published article on the topic.

[Re: Found NY style Pizza in Vegas. But, how to make dough without NYC water/flour?](#)**1689**

Roberto;

Did the shape of the pizza affect the way it tasted? If not, don't sweat it! Free form pizzas are a popular item.

Your finished pizza looks just fine, and I bet it tastes as good as it looks too. :drool:

[Re: Dough testing and procedure from Austria ;\)](#)**1690**

Have used them for many years, great performance, great price, just don't buy into the claims that you don't need to rotate/spin the pizzas during baking. Not much not to like about the ovens.

[Re: Marsal Oven](#)**1691**

Your dough ball looks great, I might suggest putting just a "wipe" of oil in the bowl before placing the dough ball in it, this will allow for an easier release (removal) of the dough from the bowl, in some cases you might be able to just invert the bowl for a few seconds or give it a tap on the counter top and the dough ball will fall out on its own giving you a nice symmetrical dough piece to open.

[Re: Dough testing and procedure from Austria ;\)](#)**1692**

That is strictly a personal preference. For me, my personal preference is for cold fermented dough. My entire 50+ year career in dough research has centered around bread and pizza (with cookies, pies, pastries, cakes, etc. tossed in for good measure) so I'm very familiar with the fermentation flavor in bread (room temperature/ambient) fermentation (which is the way most commercial breads here are made) so when I eat pizza I like to have a different flavor in the crust which is why I lean towards CF (cold fermentation) doughs. Over the years I've heard many people say their crust tastes "bready" which comes from the fact that most all Americans have consumed a substantial amount of commercially made bread in their lifetimes so they are, knowingly or unknowingly, familiar with that type of fermentation flavor and are looking for something different in their pizza crusts. Additionally, CF doughs are a lot easier to manage over an extended period of time as evidenced by the fact that most U.S. major pizza chains and pizzerias use some type of CF dough management procedure. In the end though it all boils down to personal preference, what you like and what works best for you is what you will want to use.

[Re: How should the dough after bulk look like ?](#)**1693**

Their "Bread Flour" comes in at 12 to 12.2% protein content. Their commercial equivalents would be any of the following:

Harvest King

Ben Hur

Rex Royal (slightly higher at 12.4%)

Washburn's (slightly higher at 12.4%)

Full Strength and Superlative would also be close at 12.6% protein.

[Re: What is my flour doing to my starter and IDY, and why?](#)**1694**

What dough absorption are you using and how does the dough feel as compared to using one of the other flours that is working better for you? There is a possibility that the flour has oxidized which would cause it to perform normally at first but become tight and bucky during fermentation, tight/bucky doughs resist expansion and typically produce lower than expected volume bread with a tight/dense crumb structure.

Can you provide any pictures of product made with the flour?

[Re: What is my flour doing to my starter and IDY, and why? 1695](#)

I can't answer your question without knowing how you were making the SF starter and I'm not sure I understand your question regarding the IDY.

[Re: What is my flour doing to my starter and IDY, and why? 1696](#)

Roberto;

A bulk fermented dough will look gassy if fermented for an extended period of time, that's what fermentation does.

Why bulk ferment? It's just another method of dough management used in making pizza dough, plus it provides a slightly different crust flavor than the cold fermented dough management procedure. As compared to a cold fermented dough it can be more difficult to manage as the dough can be exposed to a greater range of variables including finished dough temperature as well as ambient temperature. As for mixing the dough, the "window pane" test is for making bread, not pizza, so all you need to do is to mix/knead the dough JUST until it comes smooth, more mixing than that is not needed or desirable unless you wish to have a bread like crumb structure in the finished crust.

You say you leave the dough balls come up to room temperature, what is room temperature? The fact is that 18C is roughly 64F which is already about the ideal temperature for opening the dough into skins. (ideal temperature range for opening dough balls into skins is 50 to 60F/9.9 to 15.5C).

[Re: How should the dough after bulk look like ?1697](#)

Kelly;

First, the thermal death point for yeast is 140F so 170F is definitely out of the question. The purpose of the fermentation time (9-hours) is to allow for hydration of the flour resulting in a cohesive dough. Yes, the dough is very tough and difficult to roll out but that comes with the territory of making a cracker type crust.

Additionally, it is the effect of the rolling process that brings the dough together and further helps to make it cohesive, you really don't need a cutter pan, you can roll the dough out and drape it over a screen of desired diameter and cut the excess off using a DULL table knife or bench scraper, then transfer the dough to another baking platform or a baking stone/steel. The one change I would suggest making to the dough formula is to increase the salt level to 2% for improved crust flavor.

[Re: Cracker Crust Rise 1698](#)

1) Bought Caputo and didn't like it and trying to use it up by blending with another flour.

2) Trying to achieve a certain protein level and can't buy that flour or don't have it on hand.

I can't come up with another good excuse for blending flours. My approach has always been to find an appropriate flour for the task at hand and work with a single flour whenever possible. Blending the Caputo kinda defeats the reason why it was

purchased in the first place, which might take us back to #1.

[**Re: Mixing Flours**](#)**1699**

Higher absorption doughs tend to experience better bake-out during the baking process which is also why they also tend to give the crispiest pizzas. Lower absorption doughs resist oven spring and are more dense so they do not bake-out as well which results in a potentially less crispy and softer crust feel which is usually somewhat more chewy too.

[**Re: Types of fire/heat?**](#)**1700**

This may seem silly, but my first question is: Do any of you have any experience operating a pizzeria?

[**Re: Introduction - Potential Owner**](#)**1701**

With 15+ pounds of dough weight you can achieve a true bulk fermentation of the dough as it is large enough to not be influenced by the surrounding air temperature and it will also generate and retain the heat being generated by the yeast as it ferments (heat of metabolism). The key step to effectively managing a bulk dough like this is in consistently achieving the targeted finished dough temperature, even missing it by a few degrees can/will impact the fermentation rate of the dough.

[**Re: Immediate balling vs bulk**](#)**1702**

And because you are making a suspension (not dissolving the yeast), you will want to keep agitating the suspension (stirring or otherwise) right up to the point where you are ready to weigh out the amount of the suspension that you want to use.

[**Re: Dough Doh!**](#)**1703**

While on the island of St. Thomas I came across a pizzeria called Pizza Amore they make a great N.Y. style pizza. Water source: Since the island has no fresh water all of their potable water is processed from rain water (collected locally of course). The flour being used was General Mills All Trumps (non-bromated). I've written articles on the topic and I'm on record as saying that there is nothing special about New York City water when it comes to making a N.Y. style pizza. There is nothing magical about All Trumps flour either (bromated or non-bromated), as just about any quality high protein (13.8 or 14.2%) wheat flour will work just fine.

This is not to say that water doesn't affect the quality of a pizza dough and resulting crust (indirectly) it can and does, just read up on discussions on hard and soft water to learn more. Sulfur water is also deemed to be potable we will want to exclude that but just about anything else will work fine.

[**Re: Found NY style Pizza in Vegas. But, how to make dough without NYC water/flour?**](#)**1704**

Speaking just for myself, I've noticed that there is a decided difference between a really, really really good cookie and a really, really, really bad cookie: It takes me just a little longer to eat all of the really, really, really bad cookies. :-D :-D :-D

[**Re: Best cookie I've eaten**](#)**1705**

And you didn't invite me to share that great looking pizza with you :'(You're off to a great start! :chef:

[**Re: Thank You Tom**](#)**1706**

I would also suggest getting some litmus paper strips to monitor the pH as you go through the process.

[Re: dough with 80% starter](#)1707

I allow my doughs to cold ferment for a minimum of 24-hours but I like to leave it ferment for 48-hours whenever possible. Occasionally I'll leave it go for 72 to 96-hours. The reason for the long fermentation time is primarily to develop flavor in the finished crust. If you will read through some of the archived posts here you will find a lot of good discussion on fermentation time. When fermenting the dough you have options of cold fermentation or room temperature/ambient fermentation. Doughs that are managed at ambient temperature will provide a crust flavor that is slightly different from one that has been cold fermented, ambient temperature fermented doughs may also be more difficult to manage, especially for a beginner, as they are more temperature sensitive and can be more inconsistent in performance if not managed properly.

[Re: How long do you let your dough rest?](#)1708

Salt and sugar seldom ever do good things for a starter, ditto for yeast in a concentrated medium. Could you add the yeast and/or starter to the water with the salt/sugar? Sure you can, but Murphy's Law dictates that one day you will get distracted and leave them together in the bowl too long and impair the fermenting properties of the yeast or starter which will leave you scratching your head for a day or more trying to figure out what went wrong. Make it a good habit to keep the starter/yeast and the salt/sugar separated and avoid disappointment. Think of it like looking both ways before crossing a road, 99% of the time you can get away without doing it but then there is that one time when you should have.

I suggested a spiral mixer only because they are about as "bullet proof"/trouble free as a mixer can get. Don't just take my word for it, poll others here to see what they think about spiral dough mixers.

No need to slurry a starter, it will be worked in just fine by the normal mixing action of any mechanical mixer. When I make a starter it's pretty loose to begin with (actually it's pourable), but even a plastic starter, like a sponge will be incorporated just fine.

[Re: Salt/Yeast direct contact](#)1709

It sure wasn't me you were listening to. I always advocate getting the ENTIRE dough scaled and balled WITHIN 20 minutes of stopping the mixer. The reason for this is to get the dough balled and in the cooler before the dough begins to ferment and change in density (become less dense) which effectively makes the dough more difficult to efficiently cool for optimum shelf life properties. Before I can answer any question on bulk fermentation I need to know the size/weight of the dough that is being bulk fermented. If the dough weight is less than about 1.5-pounds you're kidding yourself with bulk fermentation as you are just fermenting a slightly larger dough ball, if you are talking about bulk fermenting 5-pounds of dough or more, that's a different story, not you can bulk ferment.

So, what's your total dough weight that you're bulk fermenting?

As for removing the dough from the fridge prior to use, you only want to leave it out long enough to reach 50 to 60F internal temperature which is usually around 2-hours, or so.

With a 70% absorption dough the autolyse is probably going to reduce the mixing time a little and possibly give you a little drier dough to work with during scaling and balling.

[Re: Immediate balling vs bulk](#)1710

The crust color developed through the addition of malt tends to be of a slightly redder hue than that developed through the addition of sucrose.

Most people would not see the difference.

[Re: Diastatic malt vs sugar in home oven](#) 1711

One of the biggest problems with any AP flour is that there is no real standard for it ("all purpose" just what is that flour intended for?) it can be milled from soft wheat varieties (think cake and pastry flours) or it can be milled from hard wheat varieties like bread flours are. This can pose a problem when changing brands of AP flour too. I've seen protein levels for AP flour from a low of something in the 9% range to as high as 11.5%, this is why some swear by AP flour while others swear at AP flours. It is also why I don't ever recommend using an AP flour. Bread flours, on the other hand, are designed for baking bread and bread like products (pizza included) and as such they are much better defined as to the type of wheat they are milled from as well as the protein content falling within a usable range for making pizza.

[Re: AP vs. Bread Flour for Sicilian-style pies](#) 1712

When hand mixing we found it best to put the salt (and sugar if used) into the bulk of the dough water then suspend the yeast (regardless of the type used) in a small portion of 95 to 100F water for ADY (ADY will need a 10-minute activation period) or IDY (IDY requires no activation period), but you can just dip a small amount of the dough water out of the bowl (before adding the salt/sugar) to suspend the CY in as it is not temperature sensitive, add the suspended yeast to the dough water containing the salt/sugar and immediately add flour and begin mixing.

When mixing by machine put the dough water in the bowl and add the salt/sugar, then add all of the flour and add the CY or IDY on top of the flour and begin mixing. If using ADY you will need to suspend it in a small portion of 95 to 100F water to hydrate/activate it, then after 10-minutes activation add it on top of the flour and begin mixing.

A sourdough can be added to the dough water when hand mixing just as the yeast suspensions are added, but when machine mixing it is better to add it on top of the flour just prior to starting the mixer.

Hopefully you're considering one of the spiral dough mixers for mixing your doughs.

[Re: Salt/Yeast direct contact](#) 1713

Before answering your question I would like to know if you are machine mixing (assuming you are) and more importantly, what type of yeast are you using?

[Re: Salt/Yeast direct contact](#) 1714

We recently had quite a bit of discussion here on DELCO pizza which might be of interest to you.

[Re: New here! Opening a new place soon!](#) 1715

Before I can really help you I've got to ask you to put your dough "recipe" into a dough "formula" based either in weight measures or bakers percent, that will help tremendously with the diagnostics allowing us to give you some meaningful direction, also it will go a long ways in helping you produce a more consistent product.

[Re: What am I doing wrong???](#)..... 1716

If you are planning to sell whole pizzas a rocker knife is fast and easy to use.

[Re: What is your favorite pizza cutter for high traffic events? 1717](#)

It would get up to full operating temperature, eventually. With the elements not generating full heat potential the oven would cool when opening the door, like you never need to do that when using a deck oven! Multiple bakes were impossible unless we waited about 15-minutes before loading the oven again as the deck was sooo ssslllooowww to recover.

What a breath of fresh air when we got the Marsal gas oven! :chef:

[Re: Wondra Flour for Pizza Crust Recipe? 1718](#)

Equal parts fat and flour/100% fat = a roux, great for thickening a gravy.

Even a pie crust with 35 to 50% fat will have some water in it to form some gluten as a binder.

From a practical standpoint 15 to 25% fat will be about the maximum amount used in making pizza crusts. A number of years ago croissant pizza crusts were popular. These were made with roughly 20 to 25% fat or which 5% was incorporated into the dough with the remainder added as hard fat flakes and incorporated into the dough at the end of the mixing stage. You saw the same dough being used by Burger King in making their breakfast sandwiches.

[Re: How much oil is enough 1719](#)

There are a whole lot of other things at play here which can cause flattening of the dough ball.

- 1) Some gluten development is needed to retain leavening gas but in pizza production it isn't as important as it is in bread production.
- 2) Flour strength will play a significant role in determining how well the dough ball retains shape during fermentation.
- 3) How tight the dough is rounded will impact how well the dough ball retains its shape.
- 4) The dough absorption also affects how well the dough ball retains its shape.
- 5) The amount of salt used also plays a role.
- 6) The amount of yeast used will have an impact.
- 7) The finished dough temperature will play a role.
- 8) The use of oil in the dough will also impact how the dough ball looks after fermentation.
- 9) Failure to cross-stack is a major contributor to dough ball collapse.
- 10) Improper (warm) cooler/fridge temperature.

Any one or combination of these factors can/will affect how the dough ball looks/perform after the fermentation period. It is impossible to say that any one factor has caused a dough ball to flatten or collapse without knowing the dough formulation, flour strength characteristics and dough management procedure in great detail.

[Re: Understanding dough ball structure 1720](#)

You will need to use about 5% oil to see a significant softening effect but if you mean creating a more tender eating crust 2% is a good starting point.

[Re: How much oil is enough 1721](#)

Damaged starch is usually limited to something between 6 and 12% in most flours (we've discussed the impact of damaged starch when it's at a high level before, very high dough absorption but the damaged starch is the first to be hydrolyzed so it

quickly releases its water turning the dough into soup). On average, gluten forming protein (VWG) has an absorption of 2 to 2.5 times its weight. The remainder of the water that we add (which isn't absorbed primarily by the protein and damaged starch) is used to adjust the viscosity of the dough.

[Re: Two different flours, same hydration question 1722](#)

JPB;

It is true that increasing the dough absorption plays a part in how well the dough opens but not as much as fermentation or relaxation time.

[Re: Time in balls vs extensibilty 1723](#)

Every flour is different and unique in it's own way, or said another way, no two flours are alike. Each and every flour will exhibit its own absorption and mixing properties, some flours exhibit sticky or slightly sticky dough characteristics which can be inherent in the flour and for all practical purposes, impossible to correct while others demonstrating the same characteristics can be addressed by changes to the dough absorption or mixing time.

Typically, a sough that is made using an autolyse (I think that's what you were referring to) will be less sticky and easier to handle than a dough made without using an autolyse.

If you are faced with a sticky dough make sure you are not adding diastatic malt in combination with a malted flour or that you are not using it in excess as too much malt will create a sticky dough condition that cannot be addressed.

[Re: Two different flours, same hydration question 1724](#)

When we had an electric deck oven and it was failing it took close to 15-minutes to bake our thin crust pizzas. We replaced it with a Marsal gas deck oven and our baking times went down be approximately 50%. Additionally, there are a good number of deck ovens in use for making pizzas that are not actually designed for making pizza, they were designed to bake bread so they will always have a steel deck and a burner BTU capacity of around 85,000 BTU. Not exactly the oven you would want to have for a high volume shop.

[Re: Wondra Flour for Pizza Crust Recipe? 1725](#)

Once the dough is balled it is typically allowed to cold ferment anything from 18 to 96-hours or more, it is then removed from the fridge and allowed to warm to 50 to 60F before opening.

If you use a different dough management procedure where the dough is fermented for a period of time prior to scaling and balling you only need to allow the dough balls sufficient rest time to relax sufficiently for ease of opening.

[Re: Time in balls vs extensibilty 1726](#)

Nick57;

It potentially could. That's how we bake pound cakes and fruit cakes in retail bakeries where we want to bake longer without overly drying out the product or developing an overly thick, heavy crust on the product. In many cases you can get the same effect by simply spraying water on the pizza or just the rim immediately before placing it in the oven.

Tom Lehmann/The Dough Doctor

[Re: Types of fire/heat? 1727](#)

Good news and bad news about burning wood with a higher moisture content.
The Good News: It will potentially give a very slight increase the moisture

content/humidity within the oven which can result in better heat transfer to the pizza and possibly shorten the baking time by a few seconds.

The Bad News: High moisture content wood does not burn as hot as dry wood thus effectively negating the good news.

Note: DO NOT confuse this with adding low pressure steam to an oven, in that case you're flooding the oven with steam which condenses on the product thus cooling it and delaying setting of the crust structure and enabling the product to be baked longer.

[Re: Types of fire/heat?1728](#)

You're on the right track, however, I might suggest that you begin your experimenting using what would be termed a strong bread type flour (12.2 to 12.8% average protein content). Make your doughs sufficiently large so as to get at least three dough balls from each dough, make a pizza from each dough ball at 48, 72 and 96-hour intervals. Always make the same pizza and photograph your results as well as entering your comments into a log book.

Have fun doing it. We look forward to hearing about your results.

[Re: Flour suggestions for NY Thin Style dough1729](#)

George;

That certainly might be, there is a reason why the manufacturers put an expiration date on their products, not that the product will fail after that date but they know, through their own testing, that they cannot ensure satisfactory product performance after that date. To further cloud the issue if the yeast packets, at any time since they were packaged, were subjected to less than ideal storage conditions the shelf life would be compromised so the yeast performance would be even poorer than expected after the expiration date.

[Re: Dough problem after bake1730](#)

- 1) Define a "rise". I know what a "full" rise is, by definition it is when the dough rises and then begins to recede on its own, this is also typically considered to be about 80% of the full fermentation time the flour can handle.
- 2) Finished dough temperature is what drives the rate of fermentation, the warmer the dough (within reason) the faster it will ferment.
- 3) Yeast needs some nutrient to sustain vigorous fermentation, this can be in the form of malted flour or added sugar.
- 4) Flour strength also plays a significant part in fermentation, the stronger the flour or the greater its tolerance to fermentation the greater the time needed to reach the first "full" rise as described above.

Dough absorption and water carrying capacity of the flour can impact the rate of fermentation too and it will also significantly impact the way the dough looks at any stage of fermentation. With high dough absorption the dough can look to be well fermented but in reality still be under fermented.

[Re: How to get multiple rises with yeast ratio1731](#)

Delivery no, customer pick-up yes. It took a bit for customers to get used to the concept but they're on board now. No customer complaints that the pizza was delivered later than promised, no complaints that the pizza was stuck to the top of the box, seldom ever a complaint, and no headaches associated with delivery. Like Walter said, if you really want a great pizza, come in and enjoy one!

[Re: Keeping pizza hot and not soggy when transporting to customers1732](#)

Dry wood and gas bake pretty similarly at the same temperatures, both release moisture into the oven as a result of combustion (assuming a direct fired oven which most home ovens are), electric ovens on the other hand create a very dry heat which conducts heat rather poorly so products baked in an electric oven typically require a longer baking time which can be as much as 20% longer than that required in a wood or gas fired oven baking at the same temperature. With wood it is also possible to have a variable in the amount of moisture in the wood being burned which can affect the way products bake. With all of this said, I've never heard of anyone adjusting the dough absorption due to the fuel being burned in the oven. However, as a rule, most wood fired ovens are operated at a higher temperature than gas ovens which allows the operator to increase the dough absorption to achieve specific finished crust characteristics not otherwise achievable when baking at lower temperatures. In this case I'm referencing baking at temperatures in the 800 to 1,000F range.

[Re: Types of fire/heat?1733](#)

George;

Your salt level is really very low at just over 1% which can result in an inconsistent fermentation rate. The next time you bake you might want to increase the salt level to 25 to 30-grams which is a more realistic level for pizza dough and as a side benefit it will improve the flavor of the baked crust. I'm guessing right now your crust has a slightly "starchy" like taste, the increased salt level will effectively address this. Additionally, how long do you pre-heat your oven prior to baking?

[Re: Dough problem after bake1734](#)

Just use clarified butter/ghee as regular butter will burn.

[Re: Help with pizza sticking to pan1735](#)

If you are making a N.Y style pizza you really need to be using a high protein content flour, something in the 12.8% to 14.2% protein content will work best for this application. In New York All Trumps flour is very popular, it has a protein content of 14.2%. An easy to find flour is Pillsbury Bread Flour aka Pillsbury Breadmaker Flour which has a protein content of about 12.2% and is available in most supermarkets.

[Re: Newbie Questions regarding Dough Recipe1736](#)

Par-bake crusts can easily be stored for up to a total of 4-days at room temperature. Not knowing the time of the year or the relative humidity of the room in which the crusts are being stored I suggest wrapping the cooled crusts in stretch wrap (not tightly) to prevent further moisture loss. Don't worry about staling, that is not an issue with pizza crusts but mold is, this is what we recommend not storing for more than 4-days since mold will usually begin colonizing on the 5th day.

If you go back in the archives here you will find more posts on par-baking pizza crusts.

[Re: Prebaking a shell and preventing burnt crust1737](#)

One thing that will usually help in cases like this is to blend at least 25% Crisco or some other plastic shortening into the oil. For example, if you make a blend of 3-ounces of oil and 1-ounce of Crisco and heat in the microwave to melt the Crisco into the oil then use this blend for your pan oil. This is a trick I learned when I was working in a bakery to prevent bread loaves from sticking in the pan.

Also, I know not what type of oil you are using but be aware that sometimes a

change in the type of oil being used will also help. Peanut oil is what has been used commercially for a good many years.

[Re: Help with pizza sticking to pan](#) **1738**

We have discussed this many time here, maybe Peter can dive back into the archived and reference some of the posts for you.

When changing a "recipe" based on volumetric portions into bakers percent it is recommended that you portion out the ingredients three times and weigh the sum on each ingredient then divide the sum by three which will give you the average ingredient weight. With all of the average ingredient weights written down we can begin changing your recipe into a dough formula based on bakers percent. Assign 100% to the flour weight as it is ALWAYS 100% regardless of the weight. Now, using your calculator, divide each ingredient weight by the weight of the flour and multiply by 100, this will give you the bakers percent for each ingredient.

Example:

Flour weight: 650-grams.

Ingredient weight: 17-grams.

Divide 17 by 650 X 100 = 2.61%

To use bakers percent:

Decide how much flour you want to use.

Tip: If you want to double the dough size just double the amount of flour. If your dough makes 3 dough balls and you want to increase the dough size to make 4 dough balls just use 1/3 more flour weight.

To calculate ingredient weights:

Put 100% next to your new flour weight, remember flour is ALWAYS 100%.

Using your calculator, enter the flour weight then press X and enter the percent of the ingredient you want the weight for then press % and read the weight of the ingredient in the display.

Example:

Your new flour weight is 975-grams.

The ingredient percent is 2.61%

975 X 2.61 (press the "%" key) and read the ingredient weight in the display.

If you are "math challenged" there are several spread sheets out there that I'm sure anyone here can direct you to that will do all the work for you, all you will need to do is plug in the flour weight, can't get much easier than that.

[Re: Help with recipe conversion from standard measurement to percentages](#) **1739**

Amen to that!

A little dusting flour or oil on your hands doesn't hurt a thing, adding more flour is a totally different thing which is what you were probably told not to do.

[Re: 73% hydration dough](#) **1740**

If it was collapsing when touched it was most likely over proofed.

What was the finished dough temperature?

How much of what kind of yeast was used?

Did you leave the container open for a couple of hours after you placed it in the fridge?

A little dusting flour or oil on your hands will go a long ways in helping you handle a soft/sticky dough.

[Re: 73% hydration dough](#) **1741**

While it was difficult to read the bag label it does not appear to indicate that the flour has been malted. If your dough formulation does not already contain at least 2% sugar you might try it again with at least 2% sugar included in your dough formulation. The cake like texture is a direct result of the baking powder contained in the flour "cocktail" as I like to call it. To improve the crumb structure increase the amount of yeast you're using. You are including yeast in the dough formulation as opposed to just adding water to the "cocktail", aren't you? If you are not doing do what you are making is reminiscent of the old Chef Boy Ardee pizza kit, but even that has some sugar in the dough formula but in this case since there is no yeast the sugar HAS TO BE dextrose/corn sugar.

[Re: King Arthur Flour's "Pizza Flour Blend": problems](#) **1742**

NO.

[Re: Dissolving Instant Yeast](#) **1743**

Rather than going into a detailed explanation, if you Google it you will find a definition of the spice "savory".

[Re: Is "Savory" really an ingredient?](#) **1744**

In a dough the water is pretty well taken up already by the flour and other ingredients, the 5-minutes mixing allows for a slow/controlled rate of yeast hydration while also at the same time ensuring thorough distribution of the yeast throughout the dough. When you put the IDY into 95F water there is no other competition for the water aside from the yeast so it hydrates much faster but as I've said numerous times before, this is also a problem in that you will get some glutathione being leached out of the yeast cells, yes, even with 95F water but the damage will be minimized.

[Re: Dissolving Instant Yeast](#) **1745**

I'd say that was a fair statement. Most pizza makers, both home and pizzeria, use IDY for its ease of use, greater consistency and long shelf life.

[Re: Different yeast](#) **1746**

That's not the question you asked, but you your "wondering" question is included in my response as I have indicated how they are used/added to the dough.

Kinda reminds me of a Little Suzie an Joke. Little Suzie comes home from school one day and asks her mother "where did I come from?" Her mother proceeds to explain the "facts of life" to her in full detail, then she asks Suzie why she asked about it, little Suzie responds "Well, my friend Johnny said he was from Pennsylvania and I was just wondering where I came from" :-D

[Re: Different yeast](#) **1747**

Compressed Yeast: C.Y./fresh yeast/wet yeast/brick yeast/block yeast.

About 70% moisture content.

Must be stored under constant refrigeration, should not be frozen in a static freezer.

Highly perishable.

Shelf life about 3-weeks.

Can be suspended in the dough water (any reasonable temperature) but usually just crumbled and added on top of the flour when machine mixing.

Active Dry Yeast: ADY/dry yeast.

About 8% moisture content.

Unopened shelf life of 6 to 12-months.

Opened shelf life of about 3-months.

Must be suspended and activated in 100 to 105F water prior to use.

Once activated it can be added directly to any reasonable temperature dough water.

Instant Dry Yeast: IDY/instant yeast.

About 3% moisture content.

Unopened shelf life 12 to 24-months.

Opened shelf life: 3 to 6-months.

Is usually added dry to the flour when machine mixing but should be suspended in 95F water when mixing doughs by hand or employing machine mixing times of less than 5-minutes.

Once the IDY is suspended in 95F water it can safely be added to the dough water at any reasonable temperature.

IDY when suspended in 95F water is to allow for hydration of the yeast, it is not to activate it as is done with ADY.

NOTE: The word "instant" in this case refers to the hydrating properties of the yeast, not the activation of the yeast.

IDY is extremely sensitive to the temperature of the water it is suspended in, even a 5F variance can/will impact yeast performance to some extent.

IDY can be used in the making of "goodie bags" whereas ADY cannot.

When an autolyse is used in making the dough the IDY can be sprinkled on top of the autolysed dough and machine mixed. Note that a minimum 5-minute mixing time is necessary.

Conversions:

CY: 16-ounces

ADY: 8-ounces

IDY: 6-ounces

[Re: Different yeast](#)1748

Maybe you have a very thin white sauce?

[Re: Crust Color Differences between Sauced and Unsauced Pizzas](#)1749

Without know which flour you are using I can only say:

Use a dough absorption of about 60%.

Cold ferment the dough for 12 to 24-hours.

Make sure you have at least 2% sugar in the dough formula or 0.25% of a 20L diastatic malt.

[Re: Crispy crust ?](#)1750

Welcome to the wonderful world of wheat flour. :)

[Re: King Arthur AP recall](#)1751

When mixing the dough by hand both types of yeast will perform very well but I tend to give the nod to the use of ADY in this application since it is designed specifically to be suspended and activated prior to use while the IDY could conceivably suffer some damage by being suspended in the water if the temperature isn't correct (it is more sensitive to the temperature of the water in which it is suspended than ADY), this is why I might give the nod to ADY over IDY

in this specific application, on the other hand the IDY has better shelf life properties so if you are planning to open a large package and use from it over a period of time the IDY might provide more consistent performance over the long haul, six of one, half a dozen of the other, take your pick.

[Re: Dissolving Instant Yeast](#)**1752**

If you are asking if the finished dough temperature influences or is influenced by the temperature at which the dough will be fermented, the answer is yes, but regardless of at what temperature the dough will be fermented, 76 to 78F is still a good target finished dough temperature but do keep in mind that when you will be fermenting at elevated temperatures such as room temperature fermentation consistency in achieving the targeted finished dough temperature is more important than the actual finished dough temperature itself. Where long dough fermentation times are employed it is the common practice to develop a targeted finished dough temperature and then adjust the yeast level to accommodate the fermentation time, when doing this the temperature of the dough must be a constant so achieving the targeted temperature is critical.

[Re: Desired Dough Temp & Fermentation Temp](#)**1753**

which "00" flour are you using?

[Re: Crispy crust ?](#)**1754**

Another thing to consider is the correct, and many time "legal" dosage for some of the more commonly encountered additive ingredients such as potassium bromate, azodicarbonamide, ascorbic acid, and L-cysteine hydrochloride which is measured in ppm (parts per million) based on the flour weight.

[Re: Caputo 00 Pizzeria vs Americana](#)**1755**

Either ADY or IDY will work equally as well in situations such as you have described, however, since ADY is designed to be pre-activated I might lean a little more towards using ADY for applications where the yeast must be suspended and activated prior to use. Why ADY over IDY in this specific application? Because, overall, IDY tends to be a little temperamental with regard to the temperature of the water it's suspended in so there exists a potential for damaging the yeast if one gets careless with the temperature of the water the yeast is put into. ADY while still responsive to water temperature is not as temperamental. In reality I'm probably "cutting hairs" since as I stated in another post recently any difference in yeast performance is going to be hard, if not impossible, to see under home baking conditions. On the other hand, if defense of IDY, it has better shelf life properties than ADY so if you do not use an entire package of ADY within a given period of time the IDY will most likely prove to provide more consistent results over a longer period of time. Like the grocer says, "six of one, half a dozen of the other", take your pick.

[Re: Dissolving Instant Yeast](#)**1756**

Walk-in coolers have significant in and out traffic during the hours the store is open and few, if any are actually operating at the set temperature, most are doing good to be operating at 50F truth be known. This would be especially so if the dough is placed anywhere near the door and the door opening isn't equipped with plastic strip curtains in addition to the regular door. We always made our dough at the end of the day when there was minimal traffic in and out of the cooler, and then there was no traffic during the night when the dough was cooling down.

[Re: Blown dough?1757](#)

Good call Peter, I totally agree. Anything over 24-hours is a bit of a stretch for a dough made with 72% absorption to begin with.

[Re: Blown dough?1758](#)

Danny;

This very topic was just discussed the other day. 0.25% of 20L diastatic malt powder is the answer you're looking for.

[Re: Caputo 00 Pizzeria vs Americana1759](#)

Your IDY is high at 0.55%. I suggest reducing it to 0.375%. One question, what is the temperature of your walk-in cooler, and what time of the day did you make the dough?

[Re: Blown dough?1760](#)

I was also thinking not more than 12-hours at room temperature or if you want to go to 24-hours use a cold fermentation procedure: Mix; scale; ball;cold ferment 24-hours; temper AT room temperature for 90-minutes, open dough balls into skins for immediate use.

[Re: Caputo flour rescue1761](#)

I agree with Rolls that for most home ovens with limited temperature capability a dough absorption in the 55 to 65% range works best. My personal "go to" absorption for most of my home pizza making is 62% absorption unless I'm trying to make something different/special like ciabatta, and even then it's only in the 70 to 75% range. You also learned a valuable lesson too, colder doughs are easier to open/handle than room temperature/ambient temperature doughs, this is why we seldom allow a refrigerated dough to warm fully back to room temperature for opening, instead we only allow the dough to warm to something in the 50 to 60F range (internal dough ball temperature) before opening it into a skin.

[Re: 80% hydration dough1762](#)

It's the temperature of the water that causes the fissures to close up so the faster you can wet the IDY the better off you'll be in the long run when the IDY is exposed to so much water all at one time.

[Re: Dissolving Instant Yeast1763](#)

Adding fat to the dough always helps to make for a softer, more tender eating crust. If you want to see first hand what fat will do just buy two packages of tortillas, one fat free the other one with normal amount of fat, you'll be surprised. Another thing to do is to add lecithin to the dough, lecithin is an emulsifier which will allow the fat to bind to the water for increased water retention.

[Re: Purposely undercooking crust1764](#)

Craig;

You thinking is spot-on, for those applications as well as those where the dough will not be machine mixed for at least 5-minutes suspending the IDY in a small amount of 95 to 100F water is the preferred way to go. You won't need to wait for it to activate, just add it to the water and stir or whisk until it is completely suspended and it's ready to add directly to the colder dough water.

[Re: Dissolving Instant Yeast1765](#)

I can't tell anything from your pictures as the slice is shown as cut from the top down. In order to tell if we are looking at a real gum line or just a false gum line I need to ask you to show a picture of the edge of the slice when cut from the bottom to the top. To do this just invert the slice and carefully cut through the crust using a VERY SHARP serrated knife or a razor knife. By cutting it in this manner you will not drag sauce and cheese down into the crumb thus obscuring vision of the important crumb just under the sauce, with that I should be able to determine just what we have going on there.

[Re: the dough underneath the sauce was still raw, what could it be ?](#) **1766**

Peter;

Sifting doesn't impact the total flour absorption, it can, and I say that cautiously, allow the flour to hydrate more quickly as there can be a greater surface area exposed to the water, but the amount of water actually absorbed (total absorption) is not affected. Lumpy/clumpy flour is a result of exposure to high humidity or Indian Meal Moth infestation (their webbs result in clumping of the flour), both of which are good signs that the flour should probably be discarded. While flour may clump as a result of packaging, the clumps readily break-up so they really don't create a problem, even when mixing totally by hand. While nobody wants to talk about it the main reason for sifting flour goes back to when baking at home was not just a hobby, but part of everyday life, the flour was stored in a metal lined deep drawer, or metal lined box and it was too valuable to throw out (for any reason) as a result the flour became infested over time and sifting made it all good again (my, how times have changed). I was raised on home made bread, the store bought bread, which was bought when we went into town every two weeks, was a treat for us kids (because it was soft) but it was an act of kindness for the women who got a reprieve from needing to bake bread for a couple of days, did I mention that our kitchen cook stove was dual fuel? Yep, dual fuel, corn cobs or wood. Mostly corn cobs as we were a small dairy farm. Now think of this, an Illinois farm, summer, hot and humid, no air conditioning and no fans and baking bread with that cook stove three times a week (need I say more?) The house was heated by dual fuel too, either corn cobs or coal (both burned long and hot, but in the winter it was always coal at night as the huge pieces that we burned lasted through the night). The farm is now a subdivision and those who live there don't have a clue about what the land once was. Sorry to digress.

[Re: Sifting](#) **1767**

As it pertains to making yeast leavened doughs, it will remove insects and larvae (worms) from the flour, it will remove any non-flour material (paper, string, etc.), it will give you a little exercise (could be a good thing) but aside from that, no, sifting flour today serves no real useful purpose.

[Re: Sifting](#) **1768**

In Chicago, Ceresota brand flour is a very popular flour to use for thin crust pizzas, it comes in at around 11.8% protein content.

[Re: Please describe the various types of thin crust pizza](#) **1769**

The "I" in IDY (instant dry yeast) stands for instant hydrating (it hydrates much faster than ADY (active dry yeast), this is why the manufacturers recommend that it be added to the flour, not to the water when making a dough. The flour will compete for the water and allow for a more controlled rate of water absorption by the IDY, if the IDY is placed into an environment where there is an abundance of water the yeast will absorb water faster than the fissures in the particles can seal

closed which allows for a flushing effect upon the yeast cells as water freely enters and leaves the cells, this flushing effect removes glutathione (the amino acid contained within the yeast cell) which severely impairs the ability of the yeast to ferment as it should. This is why if you read the direction on a 1# bag of IDY it clearly states to mix the IDY with the flour. We did studies on this many years ago at AIB and found that yeast performance became quite variable when the IDY was suspended in 60F water (average dough water temperature). We didn't do tests on water colder than that but I'll put money on the table betting that the IDY won't fare any better (probably worse) since the colder water slows the sealing of the fissures. We did look at suspending IDY in warm water and found that 95F water was the best water temperature for suspending the IDY in. It is interesting to note that when the water temperature was at 90F we found a 5% loss of gassing power from the same IDY. At 100F the gassing power was essentially the same as when the IDY was suspended in 95F water so for this reason we (and I believe the manufacturers do too) that when necessary, the IDY be suspended in 95 to 100F water.

OK, I understand that this means little to making pizza dough at home where the standard deviation is measured in light years and a 5, 10 or 15% loss of yeast gassing power will most likely go unnoticed, even a slightly softer, more extensible dough (remember that glutathione is a reducing agent, think "dead yeast") will most likely go unnoticed, so take it as you may, the IDY is still being damaged, to what extent is a great unknown and as I used to tell my students "Consistency is the most important ingredient in making pizza or any other product", without it, what do you have?

Re: Dissolving Instant Yeast **1770**

With your addition of more flour during the dough mixing (this is not recommended) it is impossible to determine just what is happening with your dough but I have a very strong suspicion that the dough "recipe" is all out of balance, because of this I'm suggesting that you start over again but this time following a known dough "recipe". After you have mastered the "recipe" we'll get you started on working with a dough "formula" which is based on ingredient weights rather than inaccurate volumetric portions. To see a dough "recipe" for home made pizza please go to the Pizza Marketing Quarterly web site at <www.pmq.com> and click on the RECIPE BANK option, once there use "home made pizza dough" for your search and you will find my home made dough recipe listed. We have used this "recipe" for many years and it works well for making both thin and thick crust pizzas. As a side note, I think you will find my dough "recipe" much easier to put together than what you have been working with.

Re: why after baking, the pizza dough is hard as rock? what mistakes am i doing? **1771**

Danny;

I sounds like a New York style crust is what you are looking for. I would suggest using a lower protein flour, possibly something in the 12% protein content range (Pillsbury Bread Flour) to reduce the chewiness to what you are looking for.

Re: Please describe the various types of thin crust pizza **1772**

From the looks of the pizza I'm guessing that it might have been baked in a very hot oven. This would allow for a short bake time resulting in reduced color to the top of the pizza while still providing a darker bottom crust color. Short baking times are notorious for giving pizzas with a soft eating characteristic and little to no crispiness in as little as a minute after baking.

[Re: Mack and Manco dough](#)**1773**

Like I said, we used 0.25% 20L malt powder to replicate typical malting done by the flour miller, 0.249 is close enough, I'm not going to argue over 0.001%

[Re: adding diastatic malt powder to my flour to match all trumps malted](#)**1774**

QJ is spot-on, you actually run the risk of damaging the IDY by putting it into suspension prior to adding it to your dough. Just add it dry right on top of the flour and it'll be just fine. That's how it is designed to be added. There are only two times when the IDY really needs to be suspended in 95F water prior to addition, one is when mixing the dough entirely by hand and the other is when mixing the dough by machine but the total mixing time will be less than a total of 5-minutes.

[Re: Dissolving Instant Yeast](#)**1775**

Unless you are approaching the absorption carrying capacity of the flour, increasing the dough absorption will contribute to a firmer, more crispy crust, but as you aptly noted, it can also become more difficult to handle.

[Re: Hydration Test](#)**1776**

Foreplease;

There is no way of telling just how much malt has been added to the flour, even the Falling Number won't help since it only provides an indication of amount of total diastatic activity (natural in the flour + added malt), not just the malt that is added by the flour miller. If you have an unmalted flour made from good, sound wheat, the addition of 0.25% of a 20L diastatic malt powder should provide the flour with a FN value something under 300 (indicating a normally malted flour). The actual amount of malt added by the miller is totally immaterial and unless you have access to a FN instrument the best you can hope for is to get close to a normally malted flour. We determined the use level of 0.25% 20L diastatic malt powder using the Amylograph instrument (prior to the invention of the Falling Number which is much faster). If you want to replicate the exact malting of a flour you first need to get a FN value of the flour, then add whatever amount of diastatic malt or amylase enzyme is needed to give the flour a FN value in the 200 to 250-second range.

[Re: adding diastatic malt powder to my flour to match all trumps malted](#)**1777**

Norma;

Yes, a Fish brand oven is a reel type oven. I'm not familiar with the pizza referenced but it might be a thin crispy type crust (typically made with 40 to 45% absorption) or a cracker type crust made with 45 to 50% absorption but mixed only 45-seconds, or so, and handled much like a long flake pie dough or possibly a biscuit dough. Both of these pizza types generally turn out pretty crispy regardless of the type of oven used. They're also great for pizza buffets too, think Mr. Ghatti's or Incredible Pizza, Pizza Street, Pizza Ranch, etc.

[Re: Purposely undercooking crust](#)**1778**

Good, open cell structure, strong bottom bake (I bet it's crispy!) and a very good top bake, (I like it that way) can't ask for much more than that! Great looking pizza! Fantastic, considering it's only your fourth attempt! :drool:

[Re: First major success](#)**1779**

Peter;

Since the term is used so frequently in reference to reel type ovens I assumed, maybe incorrectly, that it was in reference to the reel oven, but then we all know

about those who "assume". :-D

[Re: Purposely undercooking crust](#) **1780**

So you question is; Why is there a variation in the amount of flour in bags from the same delivery.

Your observations are spot on, we've seen this all the time over many years, but we don't see much variation in the actual weight of the bag when you include the tape and thread. This is why I've always advocated weighing each and every bag of flour. The variations you are encountering are from the fact that the bags are automatically filled on high speed handling equipment. While any one bag might be "off weight" if you weigh a group of ten bags the average of the ten will be correct. By the time the equipment adjusts for an off-weight the bag has already moved on and the next bag is being filled. This is why the weight seems to float between slightly heavy and slightly light with a few spot-on for good measure. It's only the bags that are out of set tolerance that are automatically pulled from the line. We've also documented that the closer you are in dough absorption to either of the extremes of high or low, the more apparent these variations become.

Also, keep in mind, as I've said so many time before, flour is not a constant, it's really quite variable. The age of the flour or wheat from which it is milled will affect it, the conditions under which it's stored will affect it, and the grist (collection of wheat varieties) from which it is milled will affect it. The millers do a great job in providing us with flour as good and consistent as it is. I have two heroes in my life, the flour miller and Betty Crocker!

[Re: Can you explain my observations?](#) **141**

When mixing dough by hand I like to add the water then the salt and sugar and the yeast (both ADY and IDY are added in a water suspension) then the flour, I then begin hand mixing to incorporate everything, then I allow the dough to rest (autolyse) for 45 to 60-minutes before continuing with my hand mixing process. When machine mixing I add the water first, then the salt and sugar followed by the flour. IDY or CY are added right on top of the flour, but ADY is added in a water suspension. Mixing is then started. If oil is used I follow the delayed oil addition dough mixing method.

[Re: Flour , water , salt, yeast. What is the right order to add them?](#) **142**

The one place where the individual tins really shine is when you're dealing with a high absorption dough.

[Re: Metal Proofing Pans vs Plastic Proofing Trays](#) **143**

I'm, still trying to find the pizza in it? :-D

[Re: Tom Lehmann's guide to burger buns](#) **144**

There are generic pizza boxes and there are pizza boxes with custom printing on them. Many pizzerias will sell advertising space on their pizza boxes to help off-set the cost of the boxes.

[Re: Pizza boxes?](#) **145**

The spots, actually "speckles" as they are referred to as are most commonly associated with oxidized particles of wheat bran, they are harmless and don't show up in the baked product. Once in a while we come across something that's similar which is caused by yeast agglomerates resulting from using ADY as one would IDY (adding it directly to the flour or dough rather than suspending it in water to

hydrate and activate prior to addition). The same can result from the addition of IDY directly to the dough and not mixing the dough long enough after the IDY addition (5-minutes is recommended). This is why my preferred method is to add the IDY directly into the flour as it's hard to go wrong that way.

[Re: Dots on pizza dough](#) **146**

Why not just make your own? A food mill will allow you to make your own from fresh or canned tomatoes.

[Re: Ground Tomatoes](#) **147**

What are the dough weights and production numbers we're looking at? Will this be for a conventional (yeast leavened) dough or a sourdough?

[Re: Rounder and divders](#) **148**

I'm not sure about hamburger buns being more "healthy" than pizza but here goes.

- 0) No "rules" or "standards" but they are expected to be soft and pliable.
 - 1) A strong bread type flour with 12 to 12.8% protein content works best.
 - 2) Typical salt level is 2%, this is to provide a controlled rate of fermentation, dough strength, and flavor to the finished bun.
 - 3) Typical sugar level is 13%.
 - 4) Dough absorption is variable between 58 and 62% depending upon the absorption properties of the flour.
 - 5) No need to use milk in a hamburger bun dough formula.
 - 6) If you want to achieve a flavor from the milk use at least 5% butter milk solids.
NOT LIQUID MILK.
 - 7) I can think of no logical reason for wanting to use milk of any kind in a hamburger bun aside from flavor see #6 above.
 - 8) Absolutely correct.
 - 9) This process is essentially a small portion of the flour made into a roux and added as an ingredient. If the flour is not malted, does not contain any amylase enzymes and has been milled from wheat with absolutely NO sprout damage it can be beneficial in making a softer bread/bun BUT if the flour has been malted or contains amylase enzymes or has been milled from wheat having ANY sprout damage the enzymes will hydrolize the damaged starch(cooked starch) in the roux converting it to sugar and releasing the water to create a wet, sticky dough.
 - 10) 4 to 6% fat is typically used.
 - 11) Today oil is mostly used as it promotes a softer crumb structure but indeed butter could be used.
 - 12) If a plastic fat is used it can be added up front but if an oil is used it should be added 1 to 2-minutes into the mixing process (delayed oil mixing procedure).
 - 13) When potato flour is used it is common to add it at 2% of the flour weight. Be sure the dehydrated potato DOES NOT contain any sulfites.
 - 14) Yes, that's how it was done prior to the advent of dehydrated potatoes.
 - 15) 80/20 Sponge & dough process with 3.5-hours sponge fermentation time.
 - 16) It provides the necessary control over fermentation to produce finished buns with the desired flavor and even more importantly, finished shape characteristics along with the resilience needed to hold up to having a hot meat patty placed in it along with high moisture content condiments without either cracking into pieces or turning soft and gummy in the consumer's hands.
- The sponge is made using 80% of the flour, 55% absorption based on sponge flour weight and 3% compressed yeast, set temperature is 75F/23.8C, sponge mix time is generally 4 to 5-minutes, sponge is then allowed to ferment for 3.5 to 4-hours, it is then brought to the mixer where it is incorporated into the remainder of the dough

ingredients and mixed to FULL gluten development and in many cases a little more. It is then given a 5 to 10-minute rest period and divided, given a final proof time of 5 to 8-minutes and rolled to a diameter slightly larger than the pan cup, it is then panned, given a final proof (100 to 105F/37.7 to 40.5C) with 86 to 88% R.H. and baked at 440F/226.6C for about 12-minutes.

17) I've not had good success making hamburger buns as described above using the cold fermentation process. The internal crumb structure is always too open and porous.

18) You are looking for a very small and fine crumb structure.

19) Each is formulated differently as there are different expectations for the finished bun.

20) Brioche Buns:

AP Flour: 100%

Salt: 2%

Butter milk (scalded): 5%

IDY: 1%

Sugar: 6.75%

Whole egg: 22%

Unsalted butter (slightly softened): 8%

Water: (100F) 50%

Place water in mixing bowl, add salt, sugar, buttermilk and beaten whole egg, add flour, IDY and butter. Mix using a flat beater until a dough is formed, allow to ferment 3 to 4-hours, scale to desired weight and form into balls, flatten balls to about 3/8-inch/9.5 mm., place on greased baking sheet and allow to proof until at least double in height, apply egg wash or milk wash, bake with steam in the oven at 400F. (if over doesn't have steam place a sheet pan filled with hot water in the oven 30-minutes prior to baking, do not remove until after the buns have been baked).

Potato Buns:

Strong bread type flour: 100%

Salt: 2.5%

Sugar: 4%

Butter: 5%

IDY: 1.25%

Re-hydrated Potato Flakes: 8%

Water: 55%

Target finished dough temperature: 80F

Remixed straight dough procedure:

Place water in mixing bowl, add salt, sugar, flour, potato, IDY and butter.

Mix to form a well incorporated dough (about 7-minutes).

Allow to ferment for 2-hours.

Remix to a smooth, extensible consistency.

Allow dough to rest for 15-minutes.

Divide into desired weight pieces and form into balls.

Allow dough balls to rest for 10-minutes (variable).

Roll out to desired diameter.

Place formed dough pieces on a greased baking sheet.

Allow to final proof (95 to 100F/35 to 37.7C) with 85 to 87% R.H. (proofing time will be variable).

Bake at 420F/215.5C for approximately 15-minutes.

Regular burger buns:

Sponge:

Flour: 80% (strong bread flour)

Water: 55% of the sponge flour weight.

Compressed Yeast: 3%

Mix together for 5-minutes (target temperature is 75F).

Allow to ferment for 3.5 to 4-hours.

Dough:

Flour: 20% (strong bread flour)

Salt: 2%

Compressed yeast: 1%

Sugar: 13%

Oil: 5%

Water: 58% based on TOTAL FLOUR WEIGHT. To find the dough water weight calculate total dough absorption and subtract the weight of water in the sponge, the remainder will be the ACTUAL amount of water to add at the DOUGH side.

Procedure:

Add the dough water to the mixing bowl, followed by the salt and sugar, then add the flour and the compressed yeast.

Mix at low speed for 2-minutes, add the oil or shortening and the fermented sponge, mix at low speed for 2-more minutes, then mix at medium speed until the dough is fully developed and extensible. Target finished dough temperature is 80F/26.6C.

Allow the dough to rest for 10-minutes, then scale into desired weight pieces and form into balls.

Allow dough balls to intermediate proof for about 8-minutes (or until they can be rolled/pinned out to desired size)

Place on greased baking sheet and allow to proof at 100 to 105F/37.7 to 40.5C for about an hour or until the buns are fully proofed.

Bake at 440F/226.6C for about 12-minutes or until the buns have a solid brown color.

21) A good replacement for egg wash is whole milk. Do you really sacrifice an egg every time you make egg wash? I just fry up what I have left over as a treat for the baker "ME" :chef:

22) Tips:

Always remove baked buns from the baking pan immediately after baking. Cool on a wire rack/screen.

Add variety to the buns by spraying them with whole milk before baking and sprinkling with sesame seeds, poppy seeds, grated Parmesan cheese, fine chopped onion, garlic, or a blend of herbs.

If the buns do not flow out sufficiently during proofing and baking (look like baseballs) the dough may need more fermentation, mixing or increased dough absorption.

I worked with Weber's Bakery in Germany helping them produce hamburger buns for their McDonald's contract back in the 80's during which time I was on the McDonalds International Bakery Products Task Force working with different baking companies world wide helping them produce hamburger buns aka "McDonalds Buns" for their McDonald's restaurants.

[Re: Tom Lehmann's guide to burger buns](#) **149**

There is also a commercial product called "Through Dough" that works quite well.

Its main use is to practice acrobatic dough tossing.

[Re: Pizza Slap Practice Dough](#)150

It would be a step in the right direction. You're at 1.25% sugar right now, I'd go to 0.5% and bench mark from there. If your flour is already malted you might be able to delete the sugar entirely if necessary.

[Re: How much Cheese on a pizza?](#)151

Oil is a lubricant and the lubricity it provides to the dough helps it to expand. Oil also helps to seal the gas cells within the dough which helps them to better retain the leavening gas produced by the yeast, together these two benefits of oil will result in improved oven spring. However, like all good things too much can be bad too. The addition of up to about 5% oil can be beneficial to oven spring but more than that could have a detrimental affect upon oven spring (it would depend upon the dough formulation). The addition of oil will also have a significant impact upon the mastication properties of the finished crust (oil it a tenderizer) but I did not address this because the question was on oven spring. Oil can also interfere with gluten development which we address through the delayed oil addition mixing method, maybe that's what happened to cause your crusts to go flat during baking?

[Re: Higher hydration doughs](#)152

Great answer!!! ^.^

Makes perfect sense.

[Re: Has anyone else had trouble since the pandemic?](#)153

The dough appears to be a little under mixed but it won't hurt in the least. It'll be just fine.

[Re: my dough balls are not baby butt smooth](#)154

Not knowing anything about your oven, but can you "dome" your pizzas to achieve the cheese melt (assuming you meant "now as opposed to not), this is done a lot of times where we need to dry off the top of the pizza to achieve the top color and cheese melt we're looking for. The moisture being released from the toppings is blanketing the top of the pizza during baking thus effectively keeping the top cool, by doming the pizza you move the pizza into the intense heat at the top of the oven at the end of the baking cycle just long enough to achieve the top characteristics you're looking for.

[Re: How much Cheese on a pizza?](#)155

It sounds just like the product RS-190 aka "dead yeast" from Lesaffre/Red Star Yeast. The active ingredient in the dead yeast is glutathione, an amino acid contained within the yeast cell. The cell membrane has been denatured allowing for the release of glutathione into the dough where it acts as a reducing agent much like L-cysteine which is the active ingredient in PZ-44, an ingredient commonly used to impart added extensibility to a dough. Too much will certainly result in a "droopy" dough condition which we used to affectionately refer to as "elephant snot". These materials are potent with actual use levels measured in ppm (parts per million) based on flour weight. Because of this the L-cysteine in PZ-44 is cut with whey to make scaling easier, the RS-190 has a lot of "fluff" remaining from the yeast cells so the material is not pure glutathione. In both cases (PZ-44 and RS-190) the recommended use level is generally considered between 1 and 2% of the flour weight. Like Brylcream, use more only if you dare. ;D

[Re: Question About Using Nutritional Yeast](#)156

That work shows what we found as a difference between "true" bulk fermentation and balled dough CF, even to the point of needing more than 24-hours CF to achieve decent finished crust characteristics (this is why I have always said that a dough that is scaled and balled right after mixing and cold fermented can be used after 24-hours but is at its best with at least 48-hours cold fermentation. We saw pizzerias go through something of a hybrid dough stage at one point where they were still bulk fermenting but placing the bulk dough in the cooler, what they accomplished was a finished dough that had bulk fermented characteristics on the inside (core) of the dough mass and CF characteristics where the dough was up against the fermentation container as this allowed heat to transfer away from the dough so the fermentation was totally different in that area, the issue now was that when the dough was used there was no way to distinguish between the two different fermented areas and they were roughly mixed together, the end result was finished pizzas with a blotchy/mottled crust color (less crust color development from the center of the dough mass due to more fermentation and less color from the outer portion of the dough mass where the dough was fermented more like we see in a CF dough). When using strong, tenacious U.S. flours fermentation is a vital key in achieving a tender eating and crispy finished crust characteristic, this is because fermentation conditions the gluten and sets the stage for the oven spring and resulting open crumb structure needed to achieve these characteristics. Weaker flours, milled from soft wheat varieties, typically yield dough that is much more extensible due to the nature of the gluten so they do not usually require a long fermentation time to achieve these characteristics but without the fermentation time there is not the same flavor development either, which is a good case for the use of a biga or sourdough starter with soft wheat flours.

[Re: Higher hydration doughs](#)157

When we did the work we saw very little difference between bulk and balled dough when the total dough weight was 1.5-Kg. The benefits of bulk fermentation come when the dough is sufficiently large so as to continue to heat up due to heat of metabolism which allows the dough to actually increase in the rate of fermentation due to its increasing temperature over the fermentation time. Smaller size doughs/dough balls simply do not have the mass to allow for this to happen and because of this the rate of fermentation is not as predictable or consistent as the dough will be more impacted by the temperature of the room. As an example, when I first started in the baking industry we used to have special rooms with highly controller temperature and humidity (fermentation rooms) just for fermenting our bulk doughs. This was all based on small scale testing that showed this was needed in order for the bulk dough to maintain a predictable/consistent rate of fermentation, then it was discovered that the mass of the bulk dough retained so much latent heat and developed such good insulating properties that it was all but impossible to impact the rate of fermentation of the dough through environmental influence. Based on this, almost overnight the fermentation rooms disappeared and doughs/sponges were bulk fermented at room temperature (regardless of whatever it might be). This practice is still in place today. This is what got us to looking at bulk v/s balled fermentation as it pertains to pizza production back in the early 80's.

[Re: Higher hydration doughs](#)158

You just want to know WHICH Caputo "00" flour you're getting as it can make a big difference in how you manage the dough.

[Re: Repacked Caputo flour](#)159

YT is good but it does have its limits....don't believe "everything" you see and hear on YT. :o

[Re: Which are the factors that affect digestibility? 160](#)

The idea is to bring the dough balls out of the cooler and allow them to warm (temper) to 50-55F at most pizzerias but at home we typically go up to 60-65F as we will only be working with a very limited number of dough balls. The dough has already been fully fermented when we remove it from the cooler and we really don't want it to ferment any more than necessary if at all possible after that. If a pizzeria were to allow the dough to come up to 75 or 80F they would need to use all of the dough within a very short period of time (well under 2-hours) or it would over proof resulting in an out of "spec." finished pizza. Additionally, the dough is extremely difficult to open when right out of the cooler and it will bubble profusely too when baked, by allowing the dough to temper as described above the dough opens much more easily and bubbling is minimized or eliminated completely. Depending upon one proficiency at opening the dough balls as well as the dough absorption, many home pizza makers find that a colder dough is easier to manage than a warmer one.

[Re: Why Does This puff Up So 1781](#)

The Roto Flex ovens are a horse of a different color than the reel type ovens, they're designed specifically for baking pizzas. Additionally, they rotate horizontally as opposed to vertically for the reel ovens.

[Re: Purposely undercooking crust 1782](#)

When baking pizzas in "reel" type ovens it is all but impossible to achieve a very crispy crust characteristic unless the pizzas are par-baked, this is why true Chicago thin crust pizzas have the unique eating properties of something approaching cooked ravioli. Those ovens were never designed for baking pizza (they're bakery ovens) but in specific applications they serve the purpose quite well.

[Re: Purposely undercooking crust 1783](#)

That's the amount you would add to an non-malted flour to achieve the same malting as used by the flour miller in making malted flour. The exact amount will occasionally be varied by the flour miller depending upon the quality (sprouting damage) of the flour he/she is milling at the moment. The more sprouting damage the less malt or amylase enzyme they will add and the less sprouting damage the more malt/enzyme they will add. High quality flour always has little to no sprouting damage but in some years, especially those where there is significant rainfall during the harvesting period, sprouting damage cannot be avoided so the miller addresses it by adjusting the malt/amylase enzyme amount that is added to the flour at the time of milling.

[Re: adding diastatic malt powder to my flour to match all trumps malted 1784](#)

I would suggest targeting a finished dough temperature of between 70 and 75F. A container that is tall, like a trash container (but approved for food contact) is better than a wide, open container since it will allow for the entrapment of carbon dioxide (heavier than air) over the dough (greenhouse effect) which will help to protect the dough from moisture loss as well as temperature changes in the room. The loose covering is only to prevent air movement in the room from disturbing this protective layer of carbon dioxide. This is how the "BIG BOYS" do it in commercial bakeries.

[Re: Proofing multiple batches](#)1785

That's an easy one to answer, use 0.083% based on the total flour weight.

[Re: adding diastatic malt powder to my flour to match all trumps malted](#)1786

If you are referring to bulk fermenting the dough (proofing is done after forming in some manner) and the time will be 24-hours or more you shouldn't have any issues with just tossing them all into a single appropriately sized container, loosely lidding/covering it and allowing it to ferment in that manner.

[Re: Proofing multiple batches](#)1787

That depends, what will the time difference be between the first dough off of the mixer and the last?

[Re: Proofing multiple batches](#)1788

If you are asking if you can suspend C.Y. in 75F water, the answer is yes. The temperature of the dough water is used to control the finished/mixed dough temperature.

Can you adjust the dough formulation so no refrigeration is required, yes you can. I'd start by adjusting the C.Y. level to about 0.15%, target a finished dough temperature of 80F (about 70F water temperature), scale and ball immediately after mixing and allow to ferment at ambient until the dough can easily be opened into skins. I can't say how long this will take as the time will vary with the strength of the flour as well as the ambient temperature. Time to roll up the sleeves and begin experimenting.

[Re: AVPN recipe](#)1789

Your procedure is a sound one that others have successfully used, but worried about the expense of the olive oil that you're brushing on the edge of the skin? OMG! How much are you using? Seriously, I can't envision you using more than a few grams at most, far less costly than the other ingredients you are putting on the pizzas for your guests. However, if this is an issue for you why not just use any low cost vegetable oil? Or how about using a blended oil such as one made by blending 20% olive oil into 80% vegetable oil. This is commonly done in cases where economy is an important factor.

Depending upon the viscosity of the sauce that you are using, pre-saucing for as much as 20-minutes before baking can lead to moisture migration into the dough which will lead to creation of a gum line after baking, you probably don't want to hear the solution to this problem but it involves the application of a very thin layer of oil to the surface of the skin prior to saucing. This very thin layer of oil creates a barrier which helps to prevent the movement of moisture from the sauce (which is about 90% water) into the dough.

Another option to explore is to utilize the assistance of a helper in preparing the pizzas. You can have everything pre-portioned for each pizza so while one pizza is being baked the next one is being prepped.

If your dough is dry enough you might also try placing the skins on seasoned pizza screens, this would allow you to fully prep all of the pizzas ahead of time (no more than absolutely necessary), and place the pizza into the oven on the screen, after a very short baking time you will be able to lift the pizza off of the screen to finish baking right on the deck. This procedure has been discussed a number of times here in earlier posts, the procedure is referred to as "decking" the pizza.

It looks like you might want to do a little experimenting in preparation for your next pizza party. :pizza:

[Re: How to prepare many pizzas in advance before baking ?](#)**1790**

One other thing, will you be machine mixing or hand kneading the dough?

[Re: Dough recipe for use in a roccbox?](#) **1791**

Before getting into the nuts and bolts of your request, you say you only have "granulated" yeast available to you. This is what us "Yanks" refer to as dry yeast. Can you tell me if it is ADY (active dry yeast), directions will call for it to be activated prior to addition to the dough, or is it IDY (instant dry yeast) not necessary to activate prior to addition to the dough. If in doubt, send a photo of the packaging and we should be able to tell.

[Re: Dough recipe for use in a roccbox?](#) **1792**

Not really. you're kinda at the mercy of your supplier unless you can see a manufactured/packaged date on the package. If there is no packaging well?????. Old time bakers used to take an egg size piece of dough immediately after mixing and form it into a ball then toss it into a bucket of warm water, if it floats in a few minutes the yeast is still alive but quality still unknown. Outside of laboratory instrumentation, that's about the best you can hope for. By the way, color and aroma are not good indicators of quality either. The one thing that does indicate sub-par quality in C.Y. is a slimy appearance and feel to the C.Y. wet and/or sticky are OK but not slimy.

My son has a place on Boot Lake, about 20-miles east of Park Rapids.

[Re: AVPN recipe](#)**1793**

No way! If, and that's a BIG "if" the yeast is fresh and hasn't been temperature abused in any way, expect something more like 3-weeks shelf life. With ADY you will get 6 to 12-months and with IDY up to 12-months, assuming proper handling. Where abouts in Northern MN? Close to Park Rapids or D.L.?

[Re: AVPN recipe](#)**1794**

While I'm not familiar with the dough formulation cited, in looking at it the procedure says it all, after mixing the dough (not actually kneading) remove it from the mixing bowl and pin it out to size, place it into the prepared 14" diameter pan (1/2-cup of oil seems like a lot of oil) and allow it to proof until the dough fills the pan, then cover and place in the refrigerator for 4 to 24-hours, remove from the fridge, dress and bake.

Here are my issues with the dough formula and procedure: The formula only contains 0.89% salt which is really not enough for optimum flavor, instead it should be between 1.75 and 2.25% for best crust flavor. The temperature of the water is not cited so I would recommend using 70F water but reserve 1/4 cup heated to 100F to activate the ADY in. Once activated, the ADY can be put into the colder water in the mixing bowl. You should be looking for a finished dough temperature of about 80F after mixing. I do not recommend proofing the dough to fill the entire pan because it will continue to proof in the fridge and you need to allow space in the pan for the increase in dough volume, instead, only allow the dough to proof to filling about 1/2 of the pan, then cover and place in the fridge where it will continue to proof until the dough is sufficiently cooled to slow the rater of fermentation. Once stabilized in the fridge the dough should keep for about 24-hours without any problems. Many operators of pizzerias manage their deep-dish/pan style pizza dough in a similar manner. To use the dough just remove from the fridge, dress the fully proofed dough (be gentle) and bake.

The length of time needed to get the initial 1/2 proof will depend upon the kitchen

temperature as well as the actual finished dough temperature, expect about 45 to 60-minutes if you hit the numbers cited. How long in the fridge? I'd go at least 12-hours with 24-being even better for flavor. Deep-dish pizzas are all about the flavor of the crust (because there's so much of it) it it isn't good you have to wallow through so much of it that it destroys the pizza experience. Experiment using butter instead of oil in the dough, or how about blending some ghee into the pan oil? Have fun experimenting! You'll be rewarded with a lot of great tasting pizza! :chef:

[Re: Pan Pizza 1795](#)

CY is indeed the same animal as "fresh yeast" I used that as the yeast type since you were referencing the AVPN dough formulation which requires the use of only CY (compressed yeast)/fresh yeast/wet yeast. To use IDY (instant dry yeast) use 40% as much IDY as CY. This figures out to 0.3% IDY to replace 0.75% CY. As for your questions on the yeast levels the amounts you are referencing are for the AVPN type dough formulation, NOT the dough formulation that I provided for you. If you plan to use the supplied dough formulation used the yeast amounts cited in the dough formulation with the conversion to IDY if that's the type of yeast you wish to use.

Please note that there are two different yeast levels cited, one is for a same day dough while the other is for a 2-day (48-hour) dough.

[Re: AVPN recipe 1796](#)

Here is a one day pizza dough formula that we used in our Woodstone wood fired oven.

Flour: 100%

Salt: 2.25%

CY: 0.75%

Water: 58%

Put water (75F) in bowl, reserve a small amount for the salt, add the CY and stir to suspend the yeast in the water. Add 1/2 of the flour and stir in. Allow to rest for 30-minutes, add the salt to the reserved water and add it to the dough along with the remainder of the flour. Mix until free of lumps and allow to ferment for 1-hour, turn out of the bowl onto a floured bench and knead until smooth (about 10-minutes). Scale into desired weight pieces, form into balls, wipe the dough balls lightly with oil and place into individual plastic bread bags, pull the bag snug to the dough ball and twist the open end to form a pony tail, tuck the pony tail under the dough ball as you place it into the fridge, allow to cold ferment for at least 6-hours but can go longer. To use, remove from fridge and allow to set at room temperature for 2 to 3-hours before turning the dough ball(s) out of the bag onto a floured surface, open by hand into skin for immediate use. Once you begin opening the dough balls they will remain good to use for about 2-hours.

To make this into a 2-day dough just reduce the yeast to 0.5%. Manage the dough in the same manner except hold it for 48-hours in the cooler before use. In my opinion, a 2-day dough is MUCH better than a 1-day dough.

[Re: AVPN recipe 1797](#)

Could you please provide the specific dough formula and dough management procedure you are planning to use.

[Re: Pan Pizza 1798](#)

Your pizza looks really good. :chef:

[Re: Side crust color and dough handling](#)1799

The word "agitate" is being used as a synonym for "mix" , in many cases the mixer manufacturers refer to the different mixing attachments as agitators too. Kneading the dough by hand is a very gently way of developing the gluten, so unless you're a "gluten" for punishment and want arms that would put the village blacksmith to shame, it is all but impossible to over develop the gluten when hand kneading. The main reason for this is because kneading the dough exposes the gluten matrix to air/oxygen which repairs the gluten bonds being broken by over mixing, sorta like an endless loop. But on the other hand, high speed mixing, like when a VCM is used can easily turn an otherwise good dough into soup by over mixing, which might only take a couple of minutes.

[Re: agitating dough vs kneading](#)1800

I'm confused by your dough formula. 58% = dough absorption; 0.2% = (compressed yeast?); 0.11% = ? Salt should be in the 1.75 to 3.25% range and yeast (as compressed yeast) in the 0.175 to 0.2% range.

Are you planning to do your mixing by hand or machine for your same day dough? Do you want to stay close to the AVPN concept or are you just looking for a good same day dough for your wood fired oven?

[Re: AVPN recipe](#)1801

Diastatic (enzyme active) malt contains amylase enzymes which hydrolyze starch into sugars, it does not hydrolyze proteins. Non-diastatic malt does not contain any viable amylase so it does not hydrolyze any starch into sugar, hence non-diastatic malt is nothing more than just another sweetener (sugar).

[Re: Non-diastatic malt syrup](#)1802

Agreed, 2% would be a good starting point. The difference in dough absorption with and without malt syrup would be easily within standard deviation for absorption and undetected. Yes, you can also use molasses, just be sure it's unsulfured.

We used to use molasses or industrial grade honey (very dark) at 3% in our multi-grain crusts along with butter for the fat source.

[Re: Barley malt syrup](#)1803

Yep.

[Re: Non-diastatic malt syrup](#)1804

Actually, it's the kettling process that gives the traditional bagel that chewy texture, those that are used for making bagel sandwiches are typically made using the steaming process since it makes for a more tender eating bagel. The non-diastatic malt syrup used in a bagel formula provides for the crust color that is characteristic to a bagel and to an extent, the "nutty" flavor of the bagel. A good number of posters here have used it in their pizza doughs too.

[Re: Barley malt syrup](#)1805

Non-diastatic malt is a type of sugar. Like sucrose (table sugar) it provides residual sugar for crust browning while at the same time providing a unique "malty" (think malted milk balls/candy) flavor when used at higher levels.

[Re: Non-diastatic malt syrup](#)1806

The yeast level looks OK (but I have a question: How do you have a "preferment

without any yeast?) so I would reduce the bulk fermentation time by 8 to 12-hours and proceed from there as normal.

[Re: Was this dough overproofed? Please take a look at my latest pies with Poolish](#) **1807**

Either flat or rounded works fine. If you are tearing the bottom of the pizza when turning/spinning you are not allowing the pizza to set undisturbed long enough.

[Re: Should my metal peel have a sharpened edge?](#) **1808**

There is no seasoning of a peel but a new wood peel should be sealed using mineral oil. If you check back in the archives you should find any number of discussions on the topic including how to seal a wood peel using mineral oil. Just DON'T EVER WASH IT, wipe it down with a slightly damp towel but don't put it in the water. With time/use you may find the surface getting a bit rough, just lightly sand the top surface with a 200-grit, or finer, sand paper and reseal and you'll be good to go again.

[Re: Pizza Peel Question](#) **1809**

It does appear that the bulk dough was somewhat over fermented which is why it was so gassy and difficult to ball. When faced with that situation I normally degas the bulk dough by slapping it on the counter top several times and then proceed with scaling and balling.

[Re: Was this dough overproofed? Please take a look at my latest pies with Poolish](#) **1810**

It's in pizza dough, regardless of what it's baked in or on.

[Re: Effects of bake temps vs bake times](#) **1811**

Setting the pizza on a screen will create an air gap/thermal break which will slow down the rate at which the crust bakes thus allowing more time to get the toppings done without burning the crust.

[Re: Can't get toppings to cook no matter the temperature before crust burns](#) **1812**

Unless you are using non-diastatic malt at very high levels, above 5% the effect of the malt will be on the crust color only.

[Re: Non-diastatic malt syrup](#) **1813**

In a practical setting the answer might be no but in a research setting where we are looking for differences due to the affect of a variable which we introduced, the answer is absolutely.

[Re: Hydration Test](#) **1814**

The appearance of those pizzas is very reminiscent of diced cheese. The issue can stem from the use of frozen cheese or subjecting it to too high of a temperature during baking.

[Re: What causes "pock marks" on cheese?](#) **1815**

In a deck oven (which you have) the typical baking time is about 7-minutes. This is why you are seeing the best bake at around the 7-minuter mark. Your oven does not have the top heat capability to provide a faster bake.

[Re: Can't get toppings to cook no matter the temperature before crust burns](#) **1816**

Fat in one form or another is a pretty common ingredient in pizza doughs. It

provides lubricity to the dough, it helps to seal the gas cell within the dough for improved oven spring, it also helps to retard moisture migration from the sauce and toppings into the dough/crust, and it helps with finished pizza flavor by imparting its own unique flavor such as is the case with olive oil or non-deodorized lard or capturing and retaining flavors otherwise lost during baking. We have discussed this a number of times before and it might be included in the function of ingredients here.

[Re: Effects of bake temps vs bake times 1817](#)

Waiting for the dough to come to room temperature will involve quite a bit of additional fermentation which will become a variable with future doughs, I would suggest scaling and balling the bulk dough as soon as it comes out of the fridge as that will provide for a more consistent form of dough management.

[Re: Cold Bulk Ferment and the process 1818](#)

If the bake temperature wasn't confirmed before each bake all bets are off of the table. I withdraw my comments. Only one variable at a time is allowed.

[Re: Hydration Test 1819](#)

A couple of different things come to mind, can you provide a picture?

[Re: What causes "pock marks" on cheese? 1820](#)

My experience is that it's mostly a matter of oven temperature with #2 being baked in a hotter oven than #8, however, both fermentation and dough temperature as well as dough absorption can impact bubbling too.

[Re: Bigger black bubbles on Neapolitan 1821](#)

I can see a progression in edge thickness as the dough absorption is increased. Could tell more if the slices had been cut from the bottom as this gives a much better view of the center section of the crust.

[Re: Hydration Test 1822](#)

Your pizzas look like they were baked at too low of a temperature which would explain the dull appearance too.

[Re: not sure - stretching, baking, thickness 1823](#)

It really doesn't matter much if you take a bulk dough of that size directly to the fridge or if you allow it to ferment for a period of time prior to placing it in the fridge. If it were me, I'd scale and ball the dough immediately after mixing, and get it into the fridge right away. Let biochemical gluten development do the work for you and as an added bonus you will have better consistency in your doughs. I like to lightly oil the dough balls and place them into individual plastic bread bags as there is no cross-stacking/leaving and down-stacking involved (leaving the dough un-lidded for a couple of hours in the fridge before lidding the containers). To use the dough just remove it about 2-hours prior to use, and allow it to warm to 50 to 60F before opening the dough balls into skins.

[Re: Cold Bulk Ferment and the process 1824](#)

I don't remember, but if you contact Steve Green at PMQ Magazine <steve@pmq.com> I'm sure he can provide you with information and probably even contacts as they have a person in Japan and a presence at the show. I did a series of seminars at one of the food shows in Japan a few years ago, I no longer remember the name of the show or the venue but it was the large building shaped

like an upside down pyramid, you can't miss that building!

[Re: Dough handling+baking 1825](#)

Beg my pardon? For what? :-D Feel free to jump in at any time.

[Re: Effects of bake temps vs bake times 1826](#)

Chicago pizzas are baked for a very long time. Thin crust pizzas typically in the 25 to 30-minute range and deep-dish pizzas in the 40 to 45-minute range. I can't speak about HRI pizzas as I've done too much work for them over the years.

[Re: Effects of bake temps vs bake times 1827](#)

No, that's not what I said. What I said only applies to cracked or steel cut. Whole-wheat flour can be used at 100% to make a whole wheat crust since you can develop the gluten in the whole wheat flour it includes as a part of the flour equation so when you add up the white flour percent and the whole-wheat flour percent the sum is 100%. Due to the VERY SLOW hydration of the bran portion of the whole wheat flour it is advisable to prepare a "soaker" with water and whole wheat flour and allow this to soak for 30 to 60-minutes prior to addition to the dough. I've written an article on how to determine the absorption of whole-wheat flour and I've discussed it several times here in previous posts. If you don't get it right the finished crust will eat more like cardboard than anything else. Done correctly, whole-wheat crusts are a bit soft and chewy with a somewhat crispy outer layer.

[Re: Mixing in steel cut cracked wheat w/ 2 other flours 1828](#)

That is a very high and broad protein range for an A.P. flour. The problem is, do you know anything about their cake flour? High ratio cake flour or low ratio cake flour? There's a HUGE difference. Is their cake flour milled from hard or soft wheat varieties? BIG difference. Minnesota Girl (11.8% +/-) or Buccaneer (11.4 +/-) would be a much better route to go without the need to blend. Do you have any of these available to you?

[Re: Break and shred 1829](#)

To answer your question on bake time v/s temperature, bake time has the greatest impact upon the crispiness of the finished crust in respect to achieving a crispier crust as it allows more time to develop a crispy layer on the crust. Think of a Neo. pizza baked at 900+ F. It's crispy when it first comes out of the oven but within a minute or so it's like limp pasta.

The oven being references is called a "reel" oven, they're a mainstay pizza oven in Chicago.

[Re: Effects of bake temps vs bake times 1830](#)

If you want to see differences in dough absorption you really need to make 2% incremental changes.

[Re: Hydration Test 1831](#)

12% protein content flour is a bit on the high side for white pan bread. Most white pan bread producers use flour with a protein content in the 10.8 to 11.6% range. Typically, the higher the protein content the more pronounced the B&S will be.

[Re: Break and shred 1832](#)

Steel cut wheat is not considered as part of the flour equation as you will get very little gluten development from it. Instead, look at it as just another ingredient

added to the dough. Unless you want the grittiness of the steel cut wheat in the finished crust they really need to be soaked for an hour or more prior to addition to the dough. Steel cut wheat, like whole wheat will have an absorption of something close to 75%. If you will search back to previous posts on whole wheat flour you will find the procedure for determining the absorption of your specific product at hand. The best way to add the steel cut wheat is to mix the dough for about 50% and then add the soaked steel cut wheat and mix to completion. They will add a chunky texture and something of a "nutty" flavor to the finished crust.

[**Re: Mixing in steel cut cracked wheat w/ 2 other flours**](#) **1833**

As long as it is controlled, by that I mean the break isn't excessive and the shred isn't wild and the top crust is still attached. It's one of the criteria we used to quality score breads on when we offered product scoring (evaluation) as a service to the industry. Large wholesale bakeries like to minimize B&S as if you have it you must be able to control it, this is a critical aspect for them as a poor shred can have jagged pieces of crust sticking out from the loaf which will snag on the bag as the loaf is being mechanically bagged resulting in a slit in the bag and an unsaleable product. If the break is excessive the loaf may not fit into the bag, just all kinds of problems when you're bagging bread at upwards of 60 loaves per minute form a single bagging machine with multiple machines bagging 7,500 loaves per hour for each bread line.

[**Re: Break and shred**](#) **1834**

It says in the literature "room temperature" for storage. It is not recommended that you store it in the fridge as this will lead to condensation forming in the container over time which will ultimately adversely impact yeast performance. The literature also says the container has a "use by" date on it. This is all provided at the link you supplied.

One thing I might add, back in the 60's when we were looking at some of these non-domestic (for the U.S.) yeasts we found that we got slightly better shelf life by transferring the yeast to a small plastic bag and placing it back into the original container. Twist the top of the bag to close and apply the lid. This seemed to help keep moisture away from the yeast when stored for longer periods of time. I had even recommended this to the manufacturers at the time. I don't know if they ever acted on it or not.

[**Re: How do I store ADY?**](#) **1835**

So much of the answer to this question depends upon variables such as:

Strength of the flour.

Amount of yeast used.

Amount of sugar used,

Amount of salt used.

Temperature of the fridge.

How well the fridge holds a CONSTANT temperature.

Finished dough temperature.

Those are the highlights.

[**Re: Pizza dough expiration / max fermentation**](#) **1836**

Suspending IDY in cold water can result in leaching out of the glutathione from the yeast cells, IDY is especially prone to this problem due to the the "I" in its acronym. The "I" stands for instant as in instant (actually fast) hydrating. IDY should always be suspended in 95 to 100F water in cases where it needs to be suspended prior to addition to the dough.

[Re: difference between IDY and ADY \(glutenboy method vs what Gemignani says\)](#)**1837**

Remember it's designed specifically for high sugar (above 5%) dough formulations, also keep in mind that this specific type of yeast has a very low sodium tolerance. If the salt level is above 1% it will significantly impede the yeast action.

[Re: Differences in dry active yeasts?](#)**1838**

The gap between the cap and the side wall is the break and the striated portion (looks like shredded wheat) is the shred. It is a desirable feature in white bread. You can minimize it by placing the dough into the pan with the seam straight down the center of the pan. Also more mixing which creates a softer, more extensible dough will help to minimize it, while most strengthening additives will promote it as will SSL or DATEM. The use of a weaker flour will also minimize it too. Like a goof farmer takes great pride in plowing straight rows a good baker takes great pride in making loaves with about 1-inch of break and a well controlled shred.

[Re: Break and shred](#)**1839**

Because all equipment is different as are kitchens it all boils down to experiment with what you have, read/learn as much as you can and most importantly, PRACTICE, PRACTICE, PRACTICE.

[Re: The best pizza recipe regardless the price, the time, the equipement, etc.](#)
1840

While I have seen experimentally grown winter wheat flours with protein levels in the 20% range the highest commercially available flours are just a tad over 14% protein content. Most pizzas are best made with flour having a protein content in the 12 to 13% range.

[Re: Side crust color and dough handling](#)**1841**

Forget the jar, you're obsessed with the jar (sounds like a movie line), just roll the package down onto the yeast and secure with a rubber band. The package is designed to protect the contents for upwards of 6-months to a year (unopened of course) so the jar isn't serving any useful purpose unless you're pulling a vacuum on it.

[Re: Differences in dry active yeasts?](#)**1842**

Yael;

You stole my line. :-D

[Re: Side crust color and dough handling](#)**1843**

The answer to both questions is yes. You will need to experiment to find the mixing time and speed that works best for the bread. I'm guessing that you might have better luck with a spiral mixer than a planetary mixer in this case. Regarding no knead pizza dough, it's been done effectively on a commercial basis for more years than I've been around. The processing facility will have to be designed from the ground up around the process. In both cases you will most likely need to deviate from the original procedures to some extent but that goes with the scale-up.

[Re: Actually 2 questions](#)**1844**

Yep, that's why I mentioned the oven as a possible cause first,

[Re: Side crust color and dough handling](#)**1845**

My New York style pizza dough ball weights are typically based on a dough loading of 0.106-ounces per square inch regardless of the diameter.

[Re: Why Does This puff Up So](#) **1846**

Once the yeast packet is opened it is best to just discard the remainder but if you want to save it DO NOT remove it from the packet, instead just fold the packet down tightly against the yeast left in the packet and secure the folded top with a binder clip or paper clip.

[Re: Differences in dry active yeasts?](#) **1847**

Is there a reason why you are adding so much VWG? Usually half of that amount is sufficient. Additionally, you are using 70% absorption but do you realize that of that 70% the gluten by itself is accounting for nearly 20%? That means the effective dough absorption is only around 50% which would explain why the dough is so elastic. As for the white edge I'm guessing it is due to one of two things, either the oven or late/delayed oven spring. You see the same thing on hamburger buns where it is called the "break" and it forms a white ring around the circumference of the bun just below the crown. It is also present in white pan bread where we call it "break and shred", in this case it usually occurs on only one side of the loaf (but it can be present on both sides). If this is the case the cause for it is excessive dough strength (remember all that VWG? That's where it's coming from). So if that's the case, a simple reduction in VWG should address the problem. For starters I would recommend reducing the VWG to 5%, you will need to reduce the absorption at the same time so for each 1% VWG increase or decrease the dough absorption by 2%.

[Re: Side crust color and dough handling](#) **1848**

Do you know what was missing? No mention of the finished dough temperature. If the dough was ready to open in just 12-hours and the dough appeared to be gassy I'm putting my money on the horse that says your finished dough temperature was too high. The nearly 0.5% IDY didn't help matters any either. I'd suggest reducing the IDY to not more than 0.4%, adjusting the water temperature to give you a finished dough temperature of 75 to 80F, balling the dough immediately after mixing, lightly oiling the dough ball, placing it in an open bowl in the fridge for 2-hours, then covering/lidding the bowl, allow the dough to cold ferment for a minimum of 18-hours (not 12) but longer is better, bringing the dough out of the fridge for at least an hour prior to use (look for an internal dough ball temperature of 55 to 60F).

[Re: Why Does This puff Up So](#) **1849**

I was once asked this very question by a major box pizza chain, the answer was 1-hour. We mixed the dough at 95F, just barely balled it, after an hour it was opened into a skin, dressed and baked for our lunch. More typical time between balling and baking I would say is 24-hours. For me, using cold fermentation I normally use 48-hours as that is where my preference for crust flavor is at. I totally agree that there are many variables that can affect the time between balling and baking, some of those variables have to do with dough handling properties while other variables have to do with personal flavor preferences. For the shortest rest time between balling (assuming balling immediately after mixing) and baking formulate the dough with 2% compressed yeast (or equivalency in IDY or ADY), dough absorption about 60%, moderate protein content flour (11 to 12%), target a finished dough temperature of 95 to 100F, mix the dough to full gluten development, ball moderately loose, lightly oil the dough ball, it should be ready to open in 45 to 60-minutes. DO NOT complain to me about the flavor! ;D

[Re: minimum time between balling and cooking](#)**1850**

Amount of protein present in a serving divided by the serving weight (in the same weight units) X 100 will give you a very rough estimate of the amount of protein in the flour. However, this does not address the issue of gluten forming quality of the protein. This is why it is also important to know what the intended use of the flour is. An example of this would be durum semolina flour, it can have a protein content of say 13%, the same as a high protein bread type flour but in application they perform very differently.

[Re: Dough just won't come together? No gluten development?](#)**1851**

Basically, it's just a difference in moisture content of the two types of sauce. Red sauce is, on average, about 90% water so as the pizza bakes the moisture is driven off of the sauce, the moisture laden air is cooler than the surrounding air so it settles down around the pizza, enveloping it in a cooling layer of moisture laden air, thus reducing crust color development. Whit sauce doesn't have this amount of water (at least mine don't) so this cooling effect is either diminished or not in play which allows the crust to begin developing color faster with more total color development. This DOES NOT apply for baking in an air impingement oven as the high velocity airflow in these oven remove the cooling, moisture laden air (that's one of the ways they are able to bake faster than a conventional deck oven).

[Re: Crust Color Differences between Sauced and Unsauced Pizzas](#)**1852**

There are different types of dry active yeast, such as active dry yeast (ADY) and instant dry yeast (IDY) and even protected active dry yeast (PADDY) and within the IDY spectrum there are various strains for specific applications such as high sugar, and freeze tolerant and a new one that is extremely temperature sensitive. However, if you are asking if there is a significant difference in the same yeast types between the different manufacturers, the answer is no.

[Re: Differences in dry active yeasts?](#)**1853**

If you will provide your exact dough formula by weight and bakers percent as well as your complete dough management procedure I might be able to determine just what the cause is.

Tom Lehman/The Dough Doctor

[Re: Why Does This puff Up So](#)**1854**

Gluten is formed when the wheat proteins glutenin and gliadin are agitated/mixed in the presence of water. Biochemical gluten development is the result of a number of factors coming together including movement of the dough as it ferments and changes to the protein due to exposure to acids and enzymes from the yeast and byproducts of fermentation which all work together to develop gluten in either cold or warm fermented dough. Biochemical gluten development is by far, the oldest method for developing gluten, and I might add, still the best. The only reason why it isn't used more as the sole method for gluten development is due to the initial poor handling properties of the dough and the amount of time it takes to accomplish. When making yeast leavened products at home neither of these are typically an issue so the process is well implemented for home baking but it's a whole different story in a commercial setting.

[Re: Sifting and autolyse?](#)**1855**

I might suggest that you find out what flours are available to you and who the manufacturer(s) is/are and then contact the manufacturer directly and ask them

what the protein content and typical application of those flours are. You should be looking for a strong bread type flour with 12 to 13% protein content. Even here in the U.S. we find that many flour suppliers are just merchants and know little about the flour they're selling, to them flour is just flour, we have six different kinds, which one do you want? Sound familiar? Many of us here at this web site will contact manufacturers directly with questions regarding flour or whatever when we have a question.

[Re: Dough just won't come together? No gluten development?](#)**1856**

Six gallons is about 50-pounds of water but flour has a much lower density so the volume needed for 50-pounds of flour is much greater.

[Re: Flour Storage Products](#)**1857**

Cakes are a different story when it comes to sifting the flour as it helps to prevent lumps in the batter. Depending upon the type of cake being made some like to sift the flour and sugar together with the minor ingredients.

[Re: Sifting and autolyse?](#)**1858**

What he said is correct, some sourdoughs are significantly less sour/tart than others. We did a study on this quite a few years ago where we made Panatone using a sourdough and it turned out quite good. It all has to do with the bacteria that you're culturing and how it's managed.

[Re: sourdough pizza acidity / ferment identification / criscito](#)**1859**

Crispy? Crunchy Chicago style thin crust? I can't say that I've ever seen those adjectives used in the same sentence with Chicago style thin crust. The four corners (party cut) are always the first to go as they have a little something that might be construed as being crispy, but the rest of the pizza is closer to a ravioli (it's that soft). That's not to say that a crispy Chicago style pizza isn't a good thing, and it can be made, but it really isn't a Chicago style pizza when made crispy/crunchy.

[Re: crispy crumbly](#)**1860**

Sifting of flour is helpful if you are bored and have nothing else to amuse yourself with or just need the exercise. It can also be helpful if you have infested (buggy) flour or potentially infested flour and really don't want to eat the little critters or need the additional protein they contribute to the flour.

As for the autolyse, it is still used by a lot of home bread and pizza makers, especially if you are making doughs with a high absorption.

[Re: Sifting and autolyse?](#)**1861**

What was the finished dough temperature? A dough that is too warm will act exactly as you've described.

[Re: Dough deflates during cold fermentation?](#)**1862**

The honey, or dried honey (a special product designed specifically for these types of applications, is used only in the glaze. For your glaze use 100% powdered sugar, add 10% boiling water and 5% dark colored honey. Heat to 115F and adjust the final viscosity through the addition of simple syrup (2-parts sugar and 1-part water boiled together until clear) add to the icing hot. If you need to adjust the honey flavor you can replace a portion of the simple syrup with honey. Too much honey will prevent the icing from setting up resulting in a wet, sticky donut. While yeast raised donuts don't typically contain eggs they can be used. Whole egg will make

for a firmer donut crumb while egg yolk will make for a softer donut crumb. 2 to 5% egg can be used but remember to take the water content into consideration when calculating the dough absorption. Whole egg is 75% water and egg yolk is 50% water.

[Re: Dunkin' Donuts Yeasted Donuts copycat](#)1863

Michael;

There are a number of good places to find pizza peels on the Internet but for your specific application you might want to see if you can get your hands on a piece of aluminum that you can shape into a simple pizza peel for transferring the pizzas from the counter to the oven. While not a permanent piece of equipment, you can also use a piece of corrugated cardboard too, or how about 1/4-inch thick plywood, or some tempered Masonite? You will want to have your peel about an inch wider X longer than the largest size pizza you plan on making and the handle only needs to be 6 to 8-inches long, use a sanding block or file to put a mild taper on the bottom of the leading edge and you're good to go. Remember, DO NOT wash it! Only wipe it down with a slightly damp towel. If you make one out of wood you might want to seal it using white mineral oil. We have discussed this a number of times here in previous posts.

There is a food show in Japan with an American Pavilion where pizza is demonstrated along with ingredients and supplies. If you want to get information on the show contact Steve Green at PMQ Magazine <steve@pmq.com>

[Re: Dough handling+baking](#)1864

Given sufficient time either salt or sugar can kill the yeast but the greatest issue is that of damage to the yeast cells which can impair their ability to ferment a dough so what you get is inconsistent yeast performance, like previously said, not a big deal with home bakers and pizza makers but it can be a real game changer for any kind of bakery or pizzeria. Additionally, when the salt/sugar pulls moisture out of the yeast it is also removing some of the amino acid glutathione which is a reducing agent, making the dough softer and to some extent weaker. This may not be a problem for the home baker but again at the commercial level where failure is not an option it can be a game changer when the dough begins to collapse or otherwise fail out at 3 or 4-days refrigerated time.

Given the potential for damage to the yeast it is still not a good idea to allow the yeast to come into direct contact with the salt or sugar.

[Re: Salt vs.Yeast](#)1865

The first pizza slice being handled is definitely thicker across its entire cross section than the other pizza slices. The fact that it has also been docked might lead one to believe that it has been proofed prior to dressing and baking. This is common at pizzerias where they pre-open the skins which allows them to proof for a period of time prior to use.

[Re: Dough just won't come together? No gluten development?](#)1866

The foil is reflecting a lot of the heat away from the pizzas during baking so I don't recommend its use. 30-minutes is an unrealistically long baking time for anything but some of the pan pizzas, which I assume you are not making. You can bake directly on the steel unless you have some aversion to doing so, or you can bake the pizza on a piece of ovenable aka bakers parchment paper. It sounds like you may not be adding any sugar to the dough formula? If you can share your dough formula and tell us what kind of flour you're using it would also help.

[Re: Dough handling+baking](#)1867

Did I miss it or something? You don't ever mention anything about temperature in your post. Without temperature control you cannot have effective dough management. you can adjust the yeast level up or down but unless you can achieve effective dough management inconsistency will reign supreme in your land.

Forget about the ambient humidity, instead concentrate of finished dough temperature, trying to achieve a finished dough temperature in the 75 to 80F range is a good starting goal. Do this by adding flake or shaved ice to the dough water to get a temperature of 65F. For dough mixing use the delayed oil mixing procedure and assuming (we all know what that means) you are using a 60 or 80-quart planetary mixer with a reverse spiral dough arm you should put the water in the bowl first, followed by the flour then the remainder of the dry ingredients, mix at low speed just until you don't see any dry flour in the bowl (about 1.5 to 2-minutes, add the oil and mix another minute in low speed, then mix 8 to 10-minutes at medium speed or just until the dough takes on a smooth, satiny appearance. Measure the finished dough temperature. Take the dough directly to the bench, do not "pass go" do not collect \$200.00, immediately scale and ball, lightly oil each dough ball, place into your individual containers, leave the lids off for at least 2-hours before lidding. Make sure you get the entire dough processed within 20-minutes, this is an important step. This should give you a dough that will be good to use over a 3 to 4-day period with the "sweet spot" at about 48-hours. To use the dough, remove from the cooler, allow to temper AT room temperature until the internal dough temperature reaches 50F, you can then begin using the dough, it will remain good to use for the next 2 to 3-hours.

An even better method is to place the dough balls onto aluminum sheet pans and cover each pan of dough balls with a food contact approved plastic bag, place the pans of dough in a wheeled rack in the cooler, no need to cross-stack or lid anything. Follow the same procedure for using the dough. We have discussed this procedure here a couple of time in previous posts.

[Re: dialing in the dough](#) **1868**

Walter;

Wishing you a a very speedy and complete recovery!

[Re: Smiling With Hope Pizza Closing for a bit](#) **1869**

If you want to see the delayed oil addition mixing method just go to my web site <doughdoctor.com> and watch my dough making video series. You would be surprised at how few pizzeria operators actually understand very much about the technology involved in mixing dough and making pizza in general. We are trying to educate operators and we're succeeding at it too, just look at the knowledge here in dough mixing as well as at the PMQ web site <www.pmq.com>, it just takes time.

[Re: Oil in 00 dough](#) **1870**

Yep, just make sure you oil the dough balls lightly prior to placing in the bags, then just grab a bag as you need it just as you do when using dough boxes. From the time you open the first dough ball the rest will remain good to use for for 2 to 2.5-hours on average.

[Re: Dough help, still not quite right](#) **1871**

Based on a 20 degree L. malt powder use 0.25% to replicate commercial malting of the flour then add whatever amount of non-diastatic malt powder or syrup you need to achieve the desired crust color.

[Re: NY Style Dough Too Crispy](#)**1872**

Sourness from the cultured rye flour (it's quite acidic) plus fermentation from the yeast (remember it's accelerated due to the increased acidity) would create accentuated sourness over time. ?

[Re: Instant Sourdough Yeast](#)**1873**

IF the cultured rye flour is indeed inactive as stated, it's my guess that what has been observed is yeast fermentation from minute particles of the IDY which would be impossible to identify much less sort out of the mixture and the acidity of the cultured rye flour would certainly help to accelerate any yeast activity. Just my "SWAG". :)

[Re: Instant Sourdough Yeast](#)**1874**

Please send me your e-mail address at <thedoughdoctor@hotmail.com> and I'll copy you on my correspondence with the National Accounts Manager, Sandi Cazalet (she was at P.E.).

[Re: Instant Sourdough Yeast](#)**1875**

I've contacted Lesaffre and got the answer directly from the manufacturer. It contains no viable lactbacillus. It is indeed a mixture of inactive cultured rye flour and IDY.

[Re: Instant Sourdough Yeast](#)**1876**

That's a lot of baking, fine if you want it crispy but if you want the softer (fold-able) texture common to the N.Y. style pizzas you will need to bake at a higher temperature for a shorter time. This may not be possible in your oven so I would suggest adding 2% sugar to the dough formulation which will help to reduce the baking time thus giving you a softer, more pliable finished crust. One other thing, you might also try increasing the dough absorption in 2% increments as I think you might be a bit low on absorption considering the durum flour and the spelt in the dough formulation.

[Re: NY Style Dough Too Crispy](#)**1877**

Typically, thin crust pizzas are made using a higher protein content flour than thick crust/pan style pizzas are made from. That might have been the difference?

[Re: Flour](#)**1878**

Pizza, pretzels, bagels, French bread/baguette, bread sticks, and croutons can all be made using the very same basic dough formula. The only minor difference might be an adjustment in dough absorption if your pizza dough has an absorption over 55%. For home use in making croutons just form the dough into a ball, place it onto a lightly greased sheet pan, cover it with a suitably large bowl to prevent drying and allow it to proof for about 2-hours or until it at least doubles in size, then dock the dough by cutting a couple slits across the top, spray it with water and bake it at 400F until golden brown, remove from oven, cool on rack, when cooled place in the fridge overnight (place in a paper bag for best results). Then cut into 3/8 to 1/2-inch thick slices, cut each slice into 1/2-inch square cubes, transfer the cubes to a sheet pan and place in a 350F oven to toast lightly. For savory croutons place into a bowl, spray with oil (lightly) add savory as desired, cover the bowl and shake to coat the cubes. Pour out onto a cookies sheet and place back into the oven at 350F for a few minutes (just to heat the croutons up, then immediately transfer to an air tight container for storage. Store at room temperature.

[Re: Dear Dough doctor.... pizza dough leftovers1879](#)

It has to do with the U.S. labeling regulations, the "cultured rye flour" is the flavoring and the fact that the LAB is shown in brackets immediately following the cultured rye flour means that these are the ingredients used to make the cultured rye flour. You will see similar things on the label of various bakery products such as where lecithin is shown as an ingredient immediately followed by brackets showing the source of the lecithin.

[Re: Instant Sourdough Yeast1880](#)

If it's something that you just add water to to make a pizza dough, it really isn't "flour", instead it's what is referred to as a "mix", in this case a pizza dough mix because it contains other ingredients than just flour. While they may not want to share with you the amounts of those other ingredients they should be willing to tell you what those other ingredients are.

[Re: Flour1881](#)

That would be the cultured rye flour.

[Re: Instant Sourdough Yeast1882](#)

Since none of those you mentioned contains any gluten forming proteins the short answer is no, they will not work as a sole flour for making pizza crust, but for the most part they could potentially be utilized as a part of the flour blend, making a composite flour. In this capacity they might be used to replace up to about 20% of the total wheat flour.

[Re: Flour1883](#)

The "cultured rye flour" is the tip off that it's a dry, inactive sourdough material that is being added. The ingredients following it in brackets are the ingredients of the "cultured rye flour".

[Re: Instant Sourdough Yeast1884](#)

Mineral yeast food was once widely used by all bakeries across the U.S. but now most large retail bakeries as well as essentially all wholesale bakeries have eliminated using it as it has little demonstrated impact upon the dough or finished product. A typical mineral yeast food consists of calcium salts (the most effective ingredient), ammonium salts (this is where M.Y.F. got its name) and usually some type of oxidizing agent (used to be bromate) but now widely discontinued. Bakers have, for the most part, replaced M.Y.F. with calcium sulfate at 0.25 to 0.5% flour basis.

[Re: Dough just won't come together? No gluten development?1885](#)

Yael;

I agree with you on the absorption as the dough does appear to be under absorbed, with that in mind, since we don't know anything about the flour, I'm beginning to wonder if this might be one of those flours that are milled to a higher than normal level of starch damage? This would explain the abnormally high dough absorption. If my suggestion to ferment it for a couple of hours is followed this might provide some insight. If the dough softens excessively during this fermentation period the problem is most likely one of high starch damage, if it doesn't it might be a case of just poor gluten quality, remember, this is a soft wheat flour and soft wheat flours are not known for their gluten forming quality characteristics, hence their main application in cakes, cookies and pastries.

[Re: Dough Knead problem](#)**1886**

The dough looks to be very rough to me. If you are sure of your scaling weights I would suggest allowing the dough to ferment at room temperature for about 2-hours (maybe a bit longer), then turn it out of the bowl and try kneading it at that time. If this produces a better product you might then want to look at testing with a higher yeast level.

[Re: Dough Knead problem](#)**1887**

There was recently some discussion on making a sourdough starter and then drying it to be added to a dough at a later time as a flavoring material. This would work great using the poorboy's sourdough, then you can store the dried material in the fridge to be added to your emergency doughs . We have been doing this for nearly 30-years now in commercial crust production where the dough is never really fermented but yet we still want to have a decent crust flavor. As an added plus....it's a lot cheaper than what they are asking for the sourdough yeast product!

[Re: a two-hour pizza](#)**1888**

KD-8000 is also my preference in scales. It's a great scale and uses common flashlight batteries. Cost is now about \$45.00 but worth every penny. We also use it when making jerky and when canning.

[Re: Need a digital scale: looking for best value..is a Taylor what I need?](#)**1889**

Ascorbic acid is used in ppm (parts per million), a typical use level would be between 90 and 180 ppm.

[Re: Dough just won't come together? No gluten development?](#)**1890**

The size of the mixture has little to do with it, over a 24-hour period of time at ? temperature the yeast will have consumed all of the available nutrient available to it, once this happens it will begin to cannibalize itself to ? extent. due to the great number of unknowns it is safer to assume the yeast is spent and not include it in the yeast percentage.

[Re: a two-hour pizza](#)**1891**

"Proving the yeast" is rarely done in a pizzeria setting and never done in a commercial setting here in the U.S. I Europe the practice is more common.

[Re: Activating CY](#)**1892**

I think the "after taste" you are referring to is just a lack of flavor in the finished crust, most people relate it to a "starchy" taste. If you want to develop a bit more flavor and stay with a no-time type of dough process you might try using a "poor boy's sourdough". The day before you intend to make pizza, into a cereal bowl add 25-grams of flour and 25-grams of water and 1/5 to 1/4 of your total SAF IDY. Stir it together, drape it with a piece of plastic wrap and allow it to ferment at room temperature until you are ready to make pizza on the following day. To use, just pour it into your dough water but remember to reduce the dough water by 25-grams (which is already in the sourdough), use the full complement of yeast as that which is in the sourdough is pretty well shot.

If you like the flavor contribution you can experiment with different amounts of the sourdough addition.....A word of CAUTION! This can become addictive! :-D

[Re: a two-hour pizza](#)**1893**

If you provide your dough formula I can convert it to a short time dough for you.

[Re: Emergency dough in a Blackstone oven](#)**1894**

No, just double the amount that you would use for a "normal" fermentation time.

[Re: a two-hour pizza](#)**1895**

Peter;

This is a good example of where IDY is suspended in warm water and allowed to hydrate/activate prior to addition to the dough as it covers both bases for hand and machine mixing of the dough.

[Re: Activating CY](#)**1896**

For an "emergency" dough such as you are making double the yeast, cut the sugar in half, and adjust the finished dough temperature to 90 - 95F, immediately after mixing scale and ball, allow the dough to ferment for 1.5-hours, then open into skins, dress and bake. Why the double amount of 60-L malt? If it was flavor you were going for you can go with 4 to 5% non-diastatic malt for a malted milk like flavor in the finished crust.

[Re: a two-hour pizza](#)**1897**

While the vitamin C tablets are essentially the same as those intended for use as a dough strengthener, there is one significant difference, the vitamin C that you buy to take as a vitamin supplement is not micro-encapsulated so it reacts very fast in the dough, it has pretty well fully reacted by the time the dough comes off of the mixer while the micro-encapsulated form intended for use in strengthening dough doesn't fully react for at least an hour, maybe a little more.

[Re: Dough just won't come together? No gluten development?](#)**1898**

Because in the box the humidity cannot be dissipated as it is in the house. Additionally, the dough balls gain temperature and this too cannot be dissipated due to the insulating properties of the box.

[Re: Why is thee humidity higher in plastic dough boxes??](#)**1899**

Heat can very easily pass through cling wrap as it is a very poor insulator as insulators go.

Like I said previously, the environment will pretty well stabilize at about 85% R.H. without any apparent condensation, now, if you were to place that box into a cooler, as the walls of the box get colder the moisture in the box will begin to condense on the colder surface of the box walls and eventually drip onto the dough balls creating a wet, sticky mess at the time of opening them into skins.

[Re: Why is thee humidity higher in plastic dough boxes??](#)**1900**

Something else to consider is that the garlic you are adding is a reducing agent (it weakens the dough) so you might want to run a test without the addition of the garlic powder, also you are adding 3% potato flakes, check the ingredient label on the box to see if the potato flakes are sulfited (some form of sulfite, like sodium metabisulfite, would be shown as an ingredient). Sulfites are added to potato flakes to help keep them white and prevent them from turning darker in color during processing, sulfites are also a reducing agent so you want to make sure you are using a product without added sulfites. While on the topic of potato flakes, 3% potato flakes will account for about 5% absorption so your dough with 56% absorption and 3% potato flakes is going to handle more like a dough with only 50 to 51% absorption which may account for the crust not rising and baking properly, especially around the edge.

[Re: Dough just won't come together? No gluten development?](#)**1901**

I'm sorry but I don't understand "the warm air from the dough did not escape into the box". Cling wrap will allow for transmission of moisture. Just wrap something in it and place it in the freezer for a couple of months.

I don't know what your finished dough temperature was so I cannot comment but it seems to me that it might be easier to just target your finished dough temperature to be the same as the room temperature, but do keep in mind that due to the heat of metabolism the dough is warming at the rate of approximately 1F per hour which can also lead to increased humidity (warm air holds more moisture than colder air). With a RH of about 75% the dough is usually pretty easy to handle but above that things begin to get a bit dicey.

[Re: Why is thee humidity higher in plastic dough boxes??](#)**1902**

The increase in relative humidity (RH) that you are seeing is coming from your dough as it is giving up moisture to the warm air surrounding the dough balls. When you put the dough in the fridge you cooled the box as well as the air in the box but the dough balls were warmer than the air so the moisture given up by the dough condensed on the inside of the box. The air will ultimately stabilize when the RH reaches about 85 to 87%. Remember, anytime the surrounding air temperature is cooler than the dough temperature you are going to get some condensation to a greater or lesser extent.

This is why we always want to cross-stack/or leave the boxes open for a period of time when using dough boxes in the cooler/fridge as it reduces/eliminates the condensation problem.

[Re: Why is thee humidity higher in plastic dough boxes??](#)**1903**

Compressed yeast is an agglomerate of billions of yeast cells, it is not melted, nor is it dissolved, it is suspended in water (that's the correct term).

While yeast and salt can be put together in water it is generally not a good idea since if you get too much salt in the water it will damage the yeast impairing its ability to ferment. The same can be said for sugar too, so, while not necessarily deleterious to the yeast it is not a good idea to put the salt and yeast together in the water. When making sponges for making bread it is common to put salt into the sponge to help control the rate of fermentation of the sponge. A sponge for bread making will typically contain 60 to 80% of the total flour, all or most of the yeast, salt can be from none to 2% of the total flour weight and water at 50 to 55% of the weight of the flour in the sponge.

[Re: Activating CY](#)**1904**

What you are experiencing is called "raising the grain", we need to do this when refinishing gun stocks too. We wet the wood and allow it to dry, then using 220 grit or finer sand paper lightly sand off the "whiskers" as they are called, then repeat again until no more whiskers are raised, it's then time to apply any stain (only on the gun stocks, not on a peel) and the final finish which in your case should be mineral oil.

[Re: Wooden pizza peel in WFO?](#)**1905**

Rolls is absolutely correct, one thing I might add though is is you are mixing your dough totally by hand it is easier to incorporate the compressed yeast (CY) if you first suspend it in the dough water. Otherwise, just crumble it on top of the flour and begin mixing.

[Re: Activating CY](#)**1906**

Are you cross-stacking the dough boxes? If you don't cross-stack you will get condensation in the boxes which can raise havoc with opening the dough balls into skins. With cold fermentation I think the best flavor is had at between 48 and 72-hours.

[Re: Dough just won't come together? No gluten development?1907](#)

Most of my "go to" pizzas are N.Y. style and I use 10-ounces of dough for a 12-inch pizza which gives a dough loading of 0.08849 (ounces per square inch).

[Re: Dough vs peel...Pros vs well, me1908](#)

We did look at it at one time but since it is really not intended for pizza application we did not pursue any further evaluation. Our impression of the flour was that it was designed to be more of a "chef's" flour, for general use in the kitchen but not specifically as a baking flour. There were just too many other flour options that worked just as well and at a lower cost too.

[Re: Wondra Flour for Pizza Crust Recipe?1909](#)

You say "as thin as possible", there is such a thing as getting the skin too thin. Remember, thin does not equate to crispy. Thin equates to a finished crust that is crispy only for the first minute or two after removing the pizza from the oven, it then quickly picks up moisture from the air as well as the toppings and becomes quite soft, sometimes even tough and chewy.

[Re: Dough vs peel...Pros vs well, me1910](#)

Additionally, you do not want to fully develop the gluten, instead, mix the dough JUST until it takes on a smooth, satiny appearance, then as the dough is fermented biochemical gluten development will take care of the gluten development for you providing a dough with good extensibility characteristics, ready to be opened into a pizza skin for dressing and baking. If you are planning to cold ferment the dough for about 24-hours you can go with as much as 1% fresh yeast/compressed yeast/CY.

Adjust the water temperature to give you a finished dough temperature of 75 to 80F/23.8 to 26.6C. Scale and ball the dough immediately after mixing, lightly oil the dough ball and cold ferment it for at least 24-hours. I like to cold ferment my dough balls using the plastic bag method (discussed here in numerous posts), then remove the dough from the fridge and allow it to temper AT room temperature for about 60-minutes before turning it out of the bag onto a floured surface and opening it into a skin ready for dressing and baking.

[Re: Correct way to make pizza?1911](#)

The dough is SUPPOSED to tear pretty easily when it is correctly mixed. Pizza doughs are UNDER MIXED by design. With this said, biochemical gluten development takes place during the cold fermentation period giving the dough a very fine, well developed gluten structure that has very extensible characteristics. If you take a dough ball that has been cold fermented for at least 24-hours and stretch it in your hands you should be able to see a very nice, strong but yet extensible gluten film. As for the dough balls, after the cold fermentation process they should be "just kissing" as shown in your picture of the boxed dough balls. Is it possible that you are looking at this all wrong?

[Re: Dough just won't come together? No gluten development?1912](#)

I think it's a combination of two things, the Wondra Flour is milled very fine and it

is "instantized", they do this by a process of wetting the flour and then drying it again, this procedure allows the flour to hydrate more quickly.

[Re: Wondra Flour for Pizza Crust Recipe?1913](#)

Wrinkling is generally caused by the dough contracting, snapping back. A major cause of this is insufficient dough fermentation. This might be an area you would want to investigate further in your testing.

[Re: Dough vs peel...Pros vs well, me1914](#)

DOP;

SAF/Red Star/Lesaffre Yeast recommends that IDY be suspended in 95 to 100F water for addition when very short mixing times (under 5-minutes) are employed.

[Re: difference between IDY and ADY \(glutenboy method vs what Gemignani says\)1915](#)

Wondra Flour has a protein content averaging about 10.5% and is available both malted or un-malted so you will need to read the label to see if it is malted or not if that's important to you. As for formulation, any decent dough formulation should work OK but owing to the low protein content keep the finished dough temperature between 75 and 80F while keeping the total dough fermentation on the short side. I would expect that the total dough absorption would be in the 56 to 58% range. Wondra Flour is designed to hydrate quickly so it may look different in the bowl at first.

[Re: Wondra Flour for Pizza Crust Recipe?1916](#)

To begin can you share a picture of your mixer and the dough agitator with us? Also, what is the bowl capacity and what is your flour weight? How many speeds does your mixer have? At what speed are you mixing the dough?

[Re: Dough just won't come together? No gluten development?1917](#)

Just washing the hands isn't enough. you have to scrub with a hand brush and that won't even thoroughly clean the hands. Just look at your hands under a magnifying glass to understand why. Gloves make it a lot easier to clean and sanitize the hands which is why any USDA inspected processing/manufacturing facility requires that all line personnel upstream from packaging wear gloves.

[Re: Pizza shops handling raw sausage bare handed?1918](#)

It's all the cracks and fissures in our skin and under the fingernails that make our hands so difficult to clean thoroughly. Gloves eliminate 95% of that making the hands much easier to clean. Don't forget to sanitize each time after a thorough washing too, gotta do both. ;D

[Re: Pizza shops handling raw sausage bare handed?1919](#)

The only benefit that gloves provide is that your hands can be more thoroughly cleaned when wearing them. If not used properly they are of no value.

[Re: Pizza shops handling raw sausage bare handed?1920](#)

The issue isn't one of contaminating the sausage as the oven should take care of any contamination but instead it's an issue of cross contamination. Any ground meat is more prone to contamination than sliced meat but even that doesn't address the cross contamination issue. Would you ever consider putting raw sausage on a salad? Of course not but that's essentially what happens when you handle raw meat/sausage and then go directly to prepping a salad without

removing the gloves or thoroughly (operative word being "thoroughly") washing ones hands.

[Re: Pizza shops handling raw sausage bare handed?1921](#)

It all depends upon the size/weight of the dough and how well you are capable of consistently achieving the targeted finished dough temperature and to a lesser extent how consistent the room temperature will be. Since the dough is much more prone to change in the bulk form I would have to say that anytime you are bulk fermenting you are going to experience significantly more variability in the finished dough as well as the finished pizzas.

[Re: Bulk Cold Ferment vs Dough Ball Cold Ferment1922](#)

The last turn brings the smooth side back to the top and the rough side to the bottom so as the donuts are lifted out of the fryer the rough side will drain rather than hold the oil resulting in less fat absorption.

I just realized too that I forgot to add the whole eggs to the dough formula. Typically 8 to 10% whole egg is used in the dough formulation. remember that whole egg is 75% water when calculating the dough absorption.

[Re: Dunkin' Donuts Yeasted Donuts copycat1923](#)

After the poolish has matured to the desired level add it to the dough side ingredients but keep in mind that an 18-hour poolish is a long fermentation time for a poolish so in all probability the flour contained in the poolish will be "shot" as the protein will be badly degraded so I suggest not using more than 10 to 20% of the total flour in the poolish. Add the poolish to the dough ingredients as you would any other ingredient but make sure to take the water content into account when calculating the total absorption, you can then manage the dough in your usual manner.

[Re: Starter timing confusion1924](#)

Donuts are fries in one of two ways, surface frying which requires that the donut be flipped/turned so as to fry both sides. The other is to fry the donut submerged using a submersion screen on top of the donut. Submersion limits donut expansion but can contribute to uniformity of shape. A good example of submerged donuts is that of the Bismark (not the battleship, the jelly filled donut). Most Bismarks are submersion fried since the white ring due to dough expansion during surface frying will be a weak spot for the jelly to leak through during injection.

My first shop started out as a donut shop for several years until donuts became a bad thing so we transitioned into a pizza and sandwich shop. I was also a training consultant for Pillsbury when they acquired the Mr. Donut chain.

2% shortening is correct but the range can go as high as 5%.

On average, your donuts should weigh the same coming out of the fryer as the dough did when going in. Total fat absorption will be some place between 16 and 20%.

[Re: Dunkin' Donuts Yeasted Donuts copycat1925](#)

Begin your experimenting with 10% sucrose. The type of flour to use will be a strong bread flour with 12.8 to 13.2% protein content. Yeast will be about 3% CY with salt at 2%, shortening at 2% and water at about 54%. Mix to a smooth dough plus two minutes. Finished dough temperature should be 80 to 82F. After mixing allow the dough to bulk ferment for 1-hour, then divide into smaller manageable pieces and form into loaves, not balls as you will be rolling it out into a rectangular shape later on. Set the dough loaves aside, cover with a sheet of plastic and allow

to ferment again 45 to 60-minutes. Exact time may vary. Roll out dough to 3/8 to 1/2 -inch thickness and place onto an oiled pizza screen for final proofing. Proof at 85 to 90F with 75% relative humidity. Proofing time will be about 45-minutes. Fry at 365F for about 20-seconds on the first side, turn and fry about 55-seconds on the second side, turn again and fry about 30-seconds before removing from the fryer. Place onto a screen to drain. Allow donuts to cool about 1-minute before icing, this is important as the heat of the donut helps the icing flow over the donut. Use the hand dip method for icing the donuts.

[Re: Dunkin' Donuts Yeasted Donuts copycat](#)**1926**

How was the dough bulk fermented? Plastic bag, lightly covered bowl, uncovered, tightly lidded, other?

[Re: How long can we store the dough in the fridge ?](#)**1927**

SAF IDY contains sorbitan monostearate and ascorbic acid as "added ingredients" in their commercial packages of IDY. The sorbitan monostearate is used to help with rehydration of the dry yeast and the ascorbic acid is added to counter the slight reducing (dough softening) effects of the glutathione present with all forms of dry yeast.

[Re: What is the point of ADY when IDY appears to be superior?](#)**1928**

Remember what I was once told: "Every oven is a law unto itself and only itself" Literally translated: Every oven is different. You will need to experiment to find out what works best for YOUR pizza, made by YOUR dough formula, managed by YOUR procedure, in YOUR oven. I can say this though, make sure you allow the pizza to set, undisturbed after peeling it into the oven, long enough for it to release cleanly from the deck. Failure to do so will result in tearing the skin/crust as you try to move it leaving a pile of toppings on the deck while you're busy creating some new four letter words. Think of it as you would when searing a steak.

[Re: How and when to turn the pizza in the WFO oven ?](#)**1929**

Without at least the sauce on the skin it is literally impossible to learn anything from baking an un-topped skin. If you had flipped the crusts over after about 15-seconds and then baked for another 15 to 20-seconds you would have made pita not pizza. Pita is baked at 750 to 900F for 25 to 30-seconds. Just for the record, pita and pizza can be made from the same basic dough formula, (flour: 100%/Salt: 2% / CY: 1%/Water: 52% / Oil: 1% optional) it's all in how the dough is handled and baked.

[Re: Critique my dough/process - first time "experimenting"](#)**1930**

No, that's used for bread doughs. The dough should not show signs of collapse and when you begin to open it the dough will not fight you (too elastic).

[Re: Proper Quantity of yeast](#)**1931**

In one word...no. At 50F you will still get fermentation taking place.

[Re: Question about streamlining dough process](#)**1932**

I agree with Craig, especially when you consider that you can pitch both and go with a natural starter if you're so inclined and still make a great product.

[Re: What is the point of ADY when IDY appears to be superior?](#)**1933**

The highest I ever go with the salt is 2.5% and when fermenting in a similar manner I use 0.15% CY. If you go too low on the yeast you run the chance of not

having sufficient leavening power to support the weight of the topping ingredients and the pizza collapsing during baking resulting in a difficult to bake crust with the eating properties of shoe leather.

[**Re: Proper Quantity of yeast**](#)**1934**

Some pizzerias will manage their dough directly out of the walk-in cooler but to do so the type of pizza being made must accommodate dough absorptions in the 60% range and a dough sheeter will be required to open the dough into a skin. Where hand forming methods are used (the majority of pizzerias) the dough is brought out of the cooler, and allowed to warm to 50F before being used, once the dough warms to 50F it will remain good to use for up to a maximum of 3-hours. Any dough not used in this period of time can be opened into skins, placed onto screens and then into a wire tree rack, placed in the cooler and after 30-minutes covered with a food contact approved plastic bag and saved for use as pre-opened skins during the next rush period. To use these pre-opened skins they will turn them off of the screen and finish opening them to full size or just touch them up a bit before dressing and baking.

A few stores will also convert any unused dough balls into bread sticks, garlic knots, etc. These will be par-baked and only require a short finish bake at the time of final use.

[**Re: Question about streamlining dough process**](#)**1935**

IDY isn't "stronger" than ADY, it is just more concentrated as it has a lower total moisture level.

As for hydrating/activating the ADY prior to addition to the dough, it has been proven scientifically many times that overall yeast performance as well as dough consistency are improved when the ADY is hydrated in 100F water prior to addition. IDY was developed specifically for addition directly to the dough without any pre-hydration/activation. Studies that I did at AIB many years ago showed that IDY has a shelf life of up to two years while ADY has a projected shelf life of 12-months. Because of the fact that it doesn't need activation and its better shelf life properties IDY had gained a lot of popularity for use in goodie bags as well as complete pizza mixes.

[**Re: What is the point of ADY when IDY appears to be superior?**](#)**1936**

If you are making a "master poolish" 20% would be about right but if you're making pizza at home why not put all or at least half of the yeast in the poolish?

[**Re: CY % in Poolish vs. Final Dough????**](#)**1937**

As I was reading your question poaching them was exactly what I had in mind.

[**Re: Best & Fast way to prep chicken breast toppings?**](#)**1938**

Without knowing the bulk dough weight as well as the finished dough temperature and how it's being stored in the fridge it's impossible to answer your question outside of a SWAG.

IF your dough size is small, under 1Kg. in weight, there is little to no difference between fermenting the dough in bulk as opposed to fermenting it in scaled dough ball form. If your total dough weight is at or under this weight the finished dough temperature and how you are storing the dough will be the determining factors as to how long the dough can be held in the fridge.

Need more information.

[**Re: How long can we store the dough in the fridge ?**](#)**1939**

The percent dough absorption used will be determined by both the flour absorption properties as well as the style of pizza you are making. If by YOUR dough management procedure YOU find that you can open the dough balls easier using a slightly lower dough absorption, by all means do so. As for dough management with high absorption doughs, if you want you can go with an autolyse to give you a slightly easier dough to handle at the same total dough absorption. If you are looking for a dough management procedure that works well with dough absorption values up into the mid to high 60% range I can send you my Dough Management Procedure that has a very long standing track record of giving very manageable doughs for both hand and machine opening without being sticky on the peel (if you do your part). To get a copy of my Dough Management Procedure just e-mail me at <thedoughdoctor@hotmail.com> and ask for my Dough Management Procedure.

[**Re: Pedantic Question**](#) **1940**

Low calorie for pizza is all about the toppings. Here is a good dough formula:

Flour: 100% whole white wheat flour.

Salt: 1.75%

Oil: 1%

IDY: 0.375%

Water: 67% (variable)

For the toppings:

Ripe tomato slices for the sauce.

Light on the cheese.

Concentrate more on vegetable toppings.

For a meat topping consider skinless chicken breast.

NOTE: Check at your local supermarket to see if they have a Mozzarella cheese analog from Galaxy Nutritional Foods. This is a soy tofu based product with "0" cholesterol and when blended 50/50 with your regular cheese makes a decent healthy cheese alternative.

[**Re: Low Calorie Pizza**](#) **1941**

While the dough was over fermented, it was not over fermented to the point of full collapse so it appears that there was still sufficient strength left to support the weight of the toppings, that being said, fermentation develops flavor in the finished/baked crust so it would be expected to be flavorful but difficult to handle the dough. From the looks of the crumb structure it appears to be in the process of collapsing as evidenced by the thick, heavy cell walls, a reduction in yeast level should still give a good flavor but with improved handling properties and a finer, more porous finished cell structure in the crust which will most likely result in a crispier crust too.

[**Re: Did I let my dough proof too long?**](#) **1942**

The idea with the bags is to eliminate all head space within the bag, not to reduce drying but to eliminate condensation which will form within that head space. Pull the bag into direct contact with the dough ball, give it a spin to form the pony tail and tuck it under the dough ball as you place it in the cooler/fridge.

If you make a dough without yeast and allow it to set at room temperature for 24-hours you will have an un-risen dough, without any yeast after the 24-hour period. I've done it before, not on purpose, but it still came out the same way.

[**Re: Pedantic Question**](#) **1943**

Your dough will exhibit a pronounced tendency to stick to an un-seasoned screen,

pan or disk. To season your screen wipe it with salad oil and place in the oven at 425F. for about 20-minutes, remove, allow to cool for a couple minutes and repeat. After the second application you should see the aluminum taking on a slight amber tint, this will continue to darken with use. DO NOT wash any seasoned pan or screen as it can result in the seasoning coming off like a bad sunburn. Instead, if they ever need to be cleaned because debris is beginning to clog the screen openings, turn your oven to its highest setting and bake the screen for 30-minutes, then you can just tap the screen to dislodge most of the offending material and at the very worst it will now be easier to clear the openings using a common table fork.

[**Re: Lehmann's naturally leavened recipes**](#)**1944**

Could have been a typo (maybe they meant to show "1.5%") it's close to 1.47%? In any case, don't sweat it, go with the calculations.

[**Re: Bakers Percent/Formula Question**](#)**1945**

Agreed, the dough really appears to be over fermented.

The only time I ever go over 1% compressed yeast is when I'm making an emergency dough for use within about 2-hours. You don't indicate what kind of yeast you are using but even if it's compressed it's too much and if ADY or IDY waaayy too much for what you are doing.

[**Re: Did I let my dough proof too long?**](#)**1946**

Allow me to elaborate on my previous response.

The ingredient amounts can very easily be scaled up or down to give you any size dough you wish to make but the issue is in the dough management procedure (unknown to me at this time), there are some dough management procedures that just do not lend themselves to being scaled up into a production size dough as they will not be able to provide the overall dough tolerance and consistency needed in a pizzeria operation where failure or inconsistency is not an option. If you want to see a copy of a bullet proof dough management procedure that you can use as a template for developing your own effective dough management procedure feel free to contact me at <thedoughdoctor@hotmail.com> and I'll be glad to send you a copy. Just ask for my Dough Management Procedure.

[**Re: Scaling dough recipe up**](#)**1947**

Yael;

You're a pretty smart "cookie"! ^^^

You nailed it!

[**Re: Bakers Percent/Formula Question**](#)**1948**

OMG! Where to begin....

The poolish provides flavor and sets the stage for potential crispiness and to some degree tenderness. Depending upon the amount of fermentation and temperature it can also impact crust color too.

The % of poolish and its impact upon the dough are dependent upon such things as the strength of the flour, the fermentation tolerance of the flour, the amount of yeast used in the poolish, the temperature of the poolish and the fermentation time.

All I can say is that when I use a poolish with a 12.8% protein content strong bread flour I use 100% absorption, 1/2 of my yeast and 85F water. I will typically allow the poolish to ferment for about 90-minutes. I'm sure others have their own favorite ways to use a poolish.

[Re: Poolish %1949](#)

We once had a lab tech that made his pizza using ketchup for the sauce. Can't say I took an immediate liking to it.

[Re: What is the worst pizza you have eaten?1950](#)

Without knowing your dough management procedure it's impossible to say if it can be scaled up or not.

[Re: Scaling dough recipe up1951](#)

The easiest way to make a par-baked crust is to add about 1/2 of the sauce to it prior to baking, this will limit the bubbling significantly. Once it's par-baked you can store it at room temperature for up to 3-days. If you refrigerate it be sure to allow a couple hours at room temperature for the crust to warm up before adding the remainder of the sauce and dressing it for baking. Best results will be had by baking it on a pizza screen as opposed to on the deck for the final bake.

[Re: Pre-made Pizza Crust1952](#)

Whenever you want to reduce or scale up a dough in size all you need to do is to adjust the total flour weight then use bakers percent to calculate the amounts of the other ingredients. I have no idea where that dough formula is coming from? ???

[Re: Bakers Percent/Formula Question1953](#)

After any bulk fermentation process the dough is going to be gassy and difficult, if not impossible to cool for stabilization so you're going to be looking at bulk fermenting, scaling and balling and then using the dough balls within the next 2 to 4-hours or so. The only option would be to open the balls into skins as soon as possible, place onto screens for storage and place into a wire tree rack stored in the cooler, be sure to place a plastic bag over the rack after an hour to prevent drying. By opening the balls into skins they can be more efficiently cooled for holding throughout the day.

[Re: Changing recipe for bulk ferment1954](#)

Are your screens seasoned? From what I see in the picture it appears that they may not be seasoned?

[Re: Lehmann's naturally leavened recipes1955](#)

If you go to the PMQ (Pizza Marketing Quarterly) web site <www.pmq.com> and go into the Recipe Bank, use "home made pizza dough" for your search you will find my time proven home made pizza dough formula/recipe that I developed for local farm families to use when making fast and easy pizza. I use it all the time when I'm at my son's home and he wants me to make pizza for dinner.

The pizza dough mix that we used when I was a child was essentially a slightly modified baking powder biscuit mix, you can make something similar by putting together a simple pizza dough (be sure it contains some honey or corn sugar, don't use table sugar as it will not develop crust color) and replace the yeast with baking powder at 5% of the total flour weight. Mix all ingredients together, scale, ball, cover with a piece of plastic, and set aside to rest for about 20-minutes, then lightly oil your fingers and begin opening the dough onto a lightly greased pan, immediately sauce and dress as desired and bake at 425F/218C.

[Re: Kid-friendly pizza dough recipe1956](#)

After re-balling you will typically need to allow the dough ball to rest for at the

VERY MINIMUM, an hour but this can easily double in time before you can re-stretch the dough.

Is your sourdough active at refrigerated temperatures?

[Re: Lehmann's naturally leavened recipes](#) 1957

When I was a very young child I would always look forward to making pizza using the Chef BoyArdee Pizza Kit that my mother would buy from the supermarket (food store back in those days). The dough (as a dry mix, just add water) and the sauce are provided, so you just add water, mix and spread out onto an greased pizza pan or cookie sheet, add the sauce and your choice of toppings and 20-minutes later we were eating pizza. Not fancy or extravagant but for my first real introduction to making pizza it wasn't a bad experience. The good news is that you can still buy it at your local supermarket! :chef:

After the kids get the hang of making pizza you can always advance them on to making your own yeast leavened dough but if the kids attention span is anything like mine was doing that right up front would have been second only to sitting out in the yard and watching the grass grow.

[Re: Kid-friendly pizza dough recipe](#) 1958

Q.J. is spot on, consistency is the name of the game. If the cross-stacking and down-stacking are posing a problem you can always place the dough balls onto an aluminum sheet pan, lightly oil the dough balls and slip a food contact approved plastic bag over each sheet pan. This procedure has been discussed in a previous post. Store the sheet pans in a vertical pan rack for mobility and you're good to go as there is no need to cross-stack or down stack when using this process, it will cut at least two or more hours off of the process before kissing the dough good night.

[Re: Changing recipe for bulk ferment](#) 1959

You might start with this:

Flour: 100% (KABF)

Salt: 2%

Sugar: 2% (optional)

Olive oil: 2%

IDY: 0.4%

Water: 65% (70F)

Procedure:

Put water in mixing bowl first, then add the salt and flour, add the IDY on top of the flour, mix just until you don't see any dry flour in the bowl, then add the oil and mix just until the dough takes on a smooth consistency. Targeted finished dough temperature: 80F.

Immediately scale and ball, lightly oil the dough balls and place into individual plastic bread bags, twist the open end into a pony tail and tuck under the dough ball as you place it into the fridge to cold ferment for 24-hours. Remove from fridge, allow to warm AT room temperature for 1-hour, open into a skin, dress and bake. The dough, when made in this manner should be able to be used as soon as 24-hours to a far out as 48-hours, maybe a little more. This process allows you to make the dough at a time when it's convenient for you and use it anytime within the next 2-days or so.

[Re: Dough help, still not quite right](#) 1960

Your dough fermentation time seems rather short to me (lack of sufficient fermentation time is a major contributor to excessive elasticity in the dough). My

suggestion is to mix, scale, ball, and cold ferment the dough balls for 24 to 48-hours before opening them into skins and dressing for baking. If you don't want to go that route I'd suggest increasing the finished dough temperature to increase the fermentation rate. I see in your last post that you are up to 1.5% IDY which is a very high yeast level for a pizza dough, so if this doesn't improve the handling properties of the dough concentrate your efforts on either temperature or changing over to a cold fermentation process. As a last resort you might need to change your flour or flour blend to something a little weaker and better suited to your short fermentation process.

[Re: Dough help, still not quite right](#)**1961**

Craig;

That's the "Through Dough" I had previously mentioned. Back in the days of the "Pizza Cruise" excursions, classes were held using this product to teach the art of pizza tossing/spinning. For a number of years it was all the rage at Pizza Expo. The wet towel works well too but this stuff is much closer to the real thing.

[Re: Dough to throw?](#)**1962**

The idea here is to make a single dough which all contestants will have to work with. The dough has to be totally stable at room temperature so yeast is never used. Remember, it's for exhibition purposes only. The All Trumps flour was used to provide the necessary gluten for extensibility without tearing. Because there is no yeast in the dough it has to be mixed/developed to essentially full gluten development being careful not to over develop the gluten. You want to have good extensibility while still retaining sufficient elasticity so the dough will withstand the rigors of being continually tossed. We always worked with the Team to get the extensibility/elasticity balance just the way they wanted it.

[Re: Dough to throw?](#)**1963**

Anne;

I don't recommend what you are proposing for a pizzeria operation, instead, how about just adjusting your dough formula to allow you to mix, scale and ball the dough in the evening when you have the walk-in space and dough boxes available and then be able to use the dough on the following day, I'm presuming at around 11:00 a.m.? This would mean modifying your dough formulation for an 18-hour cold fermentation process. I assume you are using IDY? If that's the case the only change you will need to make will be to the dough water temperature. You will need to adjust the water temperature to give you a finished dough temperature in the 80 to 85F range. Assuming you are using a planetary mixer and a mixing time of about 10-minutes your water temperature should be between 70 and 75F. With a dough ball weight of about 10-ounces your cross-stack time will be about 2-hours.

[Re: Changing recipe for bulk ferment](#)**1964**

We used to make exhibition dough aka acrobatic dough for the U.S. Pizza Team the formula which we used was as follows:

Flour: 100% (All Trumps)

Salt: 6%

Oil: 2%

Water: 65% (variable).

You need to machine mix the dough to develop a smooth, extensible consistency.

Targeted finished dough temperature: 80F

Immediately after mixing scale and ball the dough. It will be ready to use in

approximately 30-minutes and remain good to use for ?????? If you are looking for something to practice acrobatic dough tossing you might want to look into "Through Dough".

[Re: Dough to throw?1965](#)

"Whacking" the dough down on the bench top actually helps to relax the dough for the following handling procedure. Bread bakers have been doing it for hundreds of years just prior to forming the dough ball into a shaped loaf.

Why do some do it and others don't? Habit, training, who knows? In the end you do what works for YOU and what YOU are comfortable with.

[Re: Slapping it around1966](#)

To achieve a finished dough temperature in the 70 to 75F range you will need to use colder water when making your dough. When I was working with Greenwich there in the Philippines we were using dough water in the 60F range to achieve our targeted finished dough temperature.

[Re: In need of guidance1967](#)

A little oil on the hands, wipe your hands on the dough ball(s) and drop it into the bag.....done.

We did a study a number of years ago to determine if spraying of hand wiping put more oil onto the dough ball. Spraying put significantly more oil onto the dough ball than wiping the oil on with your hands.. This was done as part of a study where we were trying to reduce the fat content of the dough as much as possible.

[Re: Oil option\(s\)1968](#)

Expense, and I've already got the salad oil so why stock yet another ingredient? Over spray can be an issue too.

[Re: Oil option\(s\)1969](#)

I've never done it before but it should give you an interesting take on a Chicago type of deep-dish pizza. Without question it should be tender and flaky. If it works for you an experiment you might want to look at would be using a double thickness (two pie skins) as this might give a crust thickness more in keeping with a Chicago style pizza.

Keep us posted on your results.

[Re: Will Tenderflake Deep Dish Pie Shells work for Chicago Deep Dish Pizza?1970](#)

The only time I use an autolyse is when I'm working with high dough absorptions (above 70%). When using a mechanical dough mixer you can use 100% of the flour in the autolyse but when hand mixing I suggest not going over 75% as the remaining flour will help to disperse the ingredients into the dough after the autolyse period. When hand mixing it takes some effort to mix the dough to a smooth consistency much less actually over mix it, and with bromated flour it is all but impossible to over mix the dough by hand.

[Re: Kneading AT and Autolysing1971](#)

Craig is correct, most, if not all planetary type mixers do have a dough weight sweet spot that falls within a fairly narrow range. I've found over the years that this applies to essentially every mixer utilizing a vertical bowl design. Spiral dough mixers which utilize a horizontal bowl design typically have a much wider dough weight range sweet spot. It all has to do with the way the dough interacts with the agitator and the bowl. In a spiral design mixer the dough reacts more with the

agitator than the bowl, hence the difference.

[Re: Murenking / Aikok dual hook mixer](#)**1972**

Victor;

Since every starter culture is different it is not unusual to achieve different flavors or magnitudes of sourness/tartness from the different cultures. The micro flora that your specific culture consists of is most likely producing a lower pH which results in the more tart flavor profile of the finished/baked crust. I would suggest using less of the starter when making your doughs. A good starting point would be to use 5% less and bench mark from there.

[Re: Sourness in Pizza Dough](#)**1973**

My personal favorite:

Death....Natures way of saying "slow down".

[Re: Life's Meaningful Quotes.....](#)**1974**

We used to demonstrate frozen dough in our pizza seminar. What we found to work quite quite well with frozen dough is to slack it out in the cooler over night on an 18 X 26 aluminum sheet pan, then bring it out of the cooler, brush the dough balls lightly with salad oil and slip a large, food contact approved, plastic bag over the sheet pan containing the dough balls, pull the bottom of the bag up over the dough balls and then bring the top down and tuck everything under the pan. Allow the dough balls to remain at room temperature for 1-hour, then place back into the cooler for 24-hours. After the 24-hour cold fermentation period the dough balls will be ready to open. Because most commercially made frozen dough contains L-cysteine you should be able to take the dough directly from the fridge to the prep-table for opening and immediate use. I would suggest using a dough docker with your frozen dough. Any dough balls not used during the first day of use can be left in the cooler for use on the following day but remember FIFO.

This process will give your frozen dough much of the flavor characteristics typically obtained with dough that's made in-house and you will also find that it's much more consistent when managed in this manner.

[Re: Pizza Dough](#)**1975**

Suggestion, have you thought about par-baking the crusts with only the sauce, then add the remainder of toppings and just finish baking. This will reduce the baking time by about 50% for most pizzas. You can make the par-baked crusts about an hour in advance of using them without any issues at all.

[Re: Multiple pizzas](#)**1976**

Craig;

I'm betting if she was on a diet that she'd have the pizza cut into only two slices!

:-D :-D :-D :-D

[Re: Food Quotes](#)**1977**

If the food was good, don't ask to see the kitchen.

I've never had a pizza I couldn't learn to like.

[Re: Food Quotes](#)**1978**

Great looking peel!

Treat it with mineral oil to protect it and it should last a very long time.

[Re: Wooden pizza peel in WFO?](#)**1979**

I think what you were seeing was the lose ends of the piece of dough being tucked into the body of the dough as it was being prepared for sheeting, this is a far stretch from actual rounding/balling of the dough.

[Re: Pizza with last minute balling ?](#)**1980**

Just as an FYI, there is essentially no difference when bulk fermenting 1.5 Kg. of dough as opposed to fermenting in dough balls. The reason for this is because up to about 1.5-Kg. dough weight a bulk dough is really nothing more than a larger size dough ball. True bulk doughs will ferment much differently than a dough ball which is the reason why so many pizzerias have transitioned away from bulk fermentation to dough ball fermentation over the past 50-years.

[Re: Higher hydration doughs](#)**161**

6C (42F) is not considered to be a safe food storage temperature. In a commercial application it is not even considered as a legal refrigerated temperature, and this doesn't take into account what happens when we are in and out of the fridge many time during the day, which Yael has alluded to. This has to be taken into account when calculating how much yeast to use as well as the total CF time. This is important if you are getting your information from a commercial (pizzeria) source where they have a commercial walk-in or reach-in cooler. Everything revolves around temperature. :-D

[Re: Which are the factors that affect digestibility?](#)**162**

I've seen nothing unusual with the exception of some spot shortages of yeast and flour early on but nothing lately.

[Re: Has anyone else had trouble since the pandemic?](#)**163**

You're going to want to scale and ball the dough and then leave it out at room temperature to relax sufficiently for opening into a skin. The only issue is that 2 to 3-hours might be a bit excessive, if it is, go ahead and open the dough when its ready and place the opened skins on a lightly floured plate or something and hold in the fridge until about 30-minutes prior to use, then remove, allow to temper AT (NOT TO) room temperature for 20 to 20-minutes, clean up the skins a bit, dress and bake as needed.

If your total dough weight will be less than about 1.5-Kg. there is little to no difference between fermenting in a ball or bulk fermenting as you don't achieve the bulk fermentation characteristics with such a small dough size (it responds more like a large dough ball).

[Re: 4 day cold ferment neapolitan](#)**164**

All cards are off the table if the pizza is not completely baked, then and only then can you begin looking at various fermentation times (keep in mind that since acid is produced as a byproduct of yeast fermentation/acids inhibit crust color development)you may need to reassess the baking of the pizzas to get it correct for the fermentation time being employed at the moment.

[Re: Which are the factors that affect digestibility?](#)**165**

That's really not a lot of fermentation time if "digestibility" is what you are looking for. Remember, fermentation is also a part of the digestion process. The enzymes convert a portion of the starch to sugar for use as a yeast nutrient and the acids produced by the yeast as a byproduct help to break-down the proteins plus there will be some proteolytic enzymes present which will also work to break-down

proteins but all of this requires some time which is why a longer fermentation time might serve you better than the short fermentation time you are presently using.

[Re: Which are the factors that affect digestibility? 166](#)

Why not just "bulk" (how much dough weight are we talking about?) and then ball and allow to rest until the dough balls can be easily opened into skins? By going to a higher dough absorption, depending upon your baking temperature) you may have a higher finished moisture content in the crust which will certainly contribute to a softer crust BUT it is a double edge sword in that it will also contribute to a tougher/chewier crust at the same time. If you want to have a softer, more tender eating finished Neo. type crust you might be better served using a lower protein content flour than what you are presently using. Keep in mind though that by doing so you may not be able to ferment the dough as long as low protein flours typically exhibit a lower fermentation tolerance as compared to higher protein content flours.

[Re: Higher hydration doughs 167](#)

Steve;

The mechanics of the finished dough temperature are as follows:

Temperature is the #1 driver of fermentation, a higher temperature will boost or speed up the rate of fermentation and a lower temperature will slow it down. Even a few degrees F. will make a difference. A warmer dough temperature than desired can result in more fermentation taking place before the dough is sufficiently cooled to control the fermentation rate, this results in two things happening, !) The dough becomes less dense and a better insulator making it even more difficult to cool, 2) As the dough is fermenting it is also gaining temperature due to heat of metabolism and this heat must be extracted in order to control the rate of fermentation during the CF period. The inverse is also true when the finished dough temperature is colder/cool than targeted. The closer your targeted finished dough temperature is to 90F the more critical the finished dough temperature is and the more important it is to keep the temperature as constant as possible. At colder finished dough temperatures, say at 70F, the yeast is not as sensitive to slight variations in temperature so we have a little more latitude in the actual temperature. This is all due to the fact that yeast, as a microbe becomes exponentially more active as the temperature of the substrate which it's in approaches 90F. This issue exists in commercial operations with both walk-in and reach-in coolers (tends to be worse in reach-in units due to their reduced efficiency over the walk-in units) but it can REALLY be a problem in home refrigerators which have a 200+ "Energy Star rating" plus they are seldom operating at peak efficiency because we are constantly opening and closing the door over the CF period of time. This is also the reason why residential refrigerators and freezers are not permitted in commercial applications, they typically don't have the reserve capacity to EFFICIENTLY handle things (dough) that are a bit warmer than desired, which results in more fermentation than anticipated at any projected point in time.

[Re: All Trumps vs Kryol for homemade NY Style 168](#)

When I make the higher absorption Neo. doughs I always start out at 75% absorption and adjust accordingly for the absorption properties of the flour from there, so I would not implement any changes, but if you want a softer, more tender eating pizza I would just add some oil to the dough formula. Start at 2% and go up from there to give you what you want, remember, as with any high absorption dough, to reduce the dough absorption by the same % as you add oil.

[Re: Higher hydration doughs](#)169

Actually, there is nothing at all wrong with taking something from different formulas and/or procedures and bringing them together to make something that is unique specifically to what you are doing, that's one of the fun aspects of making pizza (the other is eating it). The work generally centers around trying to figure out how to make those different parts all fit together and play well together to give you the pizza that you want and can make great on a consistent basis.

[Re: Reshaping Dough After Delayed Fermentation](#)170

Steve;

I apologize for the assumption. :-[

As you well know, even the yeast has to be weighed, it's the one ingredient that we typically use which can give variable results with only a small change in the amount used.

When it comes to temperature monitoring, these are the temperatures which we are usually targeting, but like so many other things pizza, they are not cast in stone, they will be somewhat variable with the type of dough management process employed as well as conditions specific to our different kitchens and equipment at hand.

Finished Dough Temperature: 70 to 75F.

Down-stack Temperature: 50 to 55F.

Cooler/fridge Temperature: <40F.

Temperature to Begin Using the Dough after Cold Fermentation: 50 to 60F.

Ideal Fermentation Temperature: 90F. & 85 to 88% R.H.

Ideal Final Proofing Temperature: 95 to 105F & 85 to 88% R.H. Note: In common practice many use 95 to 100F as the optimum "practical" final proofing temperature as R.H. (relative humidity) becomes difficult to control above 100F. I have not included baking temperatures as they are so widely variable and vary with oven type/design, pizza being made, as well as altitude above sea level.

[Re: All Trumps vs Kryol for homemade NY Style](#)171

That's a very good and valid point that Yael brings up regarding a home fridge. We encounter a similar issue in commercial practice between a reach-in cooler and a walk-in cooler with the reach-in unit not holding temperature as well as a walk-in.

[Re: Reshaping Dough After Delayed Fermentation](#)172

Do you know what the Lintner Value (degree-L) of your diastatic malt is? for a 20-L the amount needed is only 0.25% of the total flour weight (316-grams in your case) but if it's 60-L the amount would only be a third of that 0.083-gram. Maximum would be about 0.5%. The amount you are presently using is 2.2%. These numbers are based on using unmalted flour but I'm guessing your flours are all malted already so that further strengthens my case that your dough might be over malted which would be responsible for the dough balls flattening out during the CF (cold fermentation) period. You might try leaving the malt out to see if it helps.

The amount of IDY is quite high too at 3-grams for 316-grams total flour weight = 0.949% (almost three times what might be considered a "normal" level of 0.375%, this would explain why the dough balls get gassy soon after removing from the fridge. Lastly, I'd suggest measuring the actual finished dough temperature after mixing. This is important as it regulates the rate at which your dough will ferment. Ideally, you will most likely be best served with a finished dough temperature in the 75 to 80F range, whatever temperature you use remember that consistency is actually more important than the actual temperature itself.

[Re: Reshaping Dough After Delayed Fermentation](#)173

Steve;

One thing that you might want to do is to begin transitioning from a dough "recipe" in volumetric portions to a dough "formula" based on actual weight for each ingredient. These are any number of good scales available on the Internet that many of us here use (I personally love my KD-8000). This change will give you the accuracy and repeatability needed to develop your dough formula(s). A good dial/stem type thermometer for \$7 to \$12.00 will take care of your temperature needs (be sure to look for one with a hex nut under the head as this will allow you to calibrate the thermometer as needed). Once you have your dough based on weight measures it can be put into bakers percent for ease of evaluation and it will greatly help you manipulate the size of the dough too if you should want to increase or decrease the actual dough size.

[Re: All Trumps vs Kryol for homemade NY Style](#)174

In reading your post I have some questions, what was the actual finished dough temperature for the Kyrol and All Trumps doughs? Did you optimize the dough absorption for the All Trumps flour or did you just plug in the same absorption you used with the Kyrol flour? I ask these questions because some of what you mentioned could be due to a difference in fermentation between the two doughs resulting from a difference in finished dough temperature which could have a significant impact upon the dough depending upon how you are managing your doughs. The dough absorption can also be highly variable especially in view of the fact that you are dealing with different brands as well as different suppliers, not to mention the fact that the absorption of any flour can/will vary from bag to bag or lot to lot, and even the age of the flour will have a significant impact upon its performance in both the dough as well as the finished crust. As you can see, there are a lot of variables at play here.

[Re: All Trumps vs Kryol for homemade NY Style](#)175

I'm suspecting some major problem/problems with your dough formula/recipe. Please provide details of your flour, dough, dough temperature, and how you are baking the pizzas and I'll be glad to offer my suggestions.

[Re: Reshaping Dough After Delayed Fermentation](#)176

The two factors most responsible for "digestibility" of the crust are fermentation and quality of bake. The longer the dough is fermented (within reason) and the more solid (complete) the bake is the more digestible the finished crust will be. From your pictures I'm guessing that your targeting too thick of a crust for high temperature baking which can easily result in not getting the finished crust as well baked as it could be.

[Re: Which are the factors that affect digestibility?](#)177

The 50 to 55F dough ball temperature after cold fermentation is the internal dough ball temperature. Depending upon your ability level at opening the dough into skins you may find it easier to open the dough at 50 to 55F or at a higher temperature as the dough becomes softer and more extensible at the higher temperatures which can be problematic for someone without the skill set to open the softer dough.

[Re: Dough science - minutes after cold ferment but before baking?](#)178

I'm in agreement with Yael in his assessment that your dough might be over

fermented at 72-hours room temperature fermentation, especially in view of the fact that we don't know the dough temperature or the room temperature. Your IDY amount (1/6th of a Tsp.) works out to 0.5-gram, and assuming 152-grams of flour in your 1-cup portion this works out to 0.328% IDY. This is very close to the accepted amount to use for the same length of fermentation time in the cooler/fridge, not at room temperature, unless room temperature is defined as <40F. If you don't want to cold ferment I'd suggest dialing the room temperature back to 24-hours and if that works for you then begin increasing the fermentation time in 12-hour increments to find what works best for you. While doing this though I would highly advise that you keep track of the finished dough temperature as well as the room temperature as both are highly prone to changing over time.

[Re: I haven't been able to duplicate my bubble crust after succeeding once.](#)**179**

Not more than 0.5%. The numbers I gave are representative of what it takes to replicate the malting of the flour that takes place at the flour mill.

[Re: Getting crust to brown without being to overcooked and hard.](#)**180**

Plus, you can fit the dough balls in between the other stuff in the fridge or even place them on top of other things. They're actually easier to fit into a small fridge than a larger size bowl, not to mention that they will cool down more efficiently than a single larger size dough. Bring the individually bagged dough balls out of the fridge to warm to at least 50F prior to opening, some like to allow the dough to warm to 60F (Note: this is in reference to internal dough ball temperature), but depending upon your skill level at opening the dough balls into skins you might want to experiment with the temperature. The colder the dough is the easier it is to handle but it can be more difficult to open as the dough tends to be more elastic when cold. By allowing the dough to warm up a bit it becomes softer and more extensible which is easier to open if you have the necessary skill-set.

[Re: Why shape dough into balls before fermenting?](#)**2001**

If you are looking for an oil to use to seal a wood work surface look no further than plain old white mineral oil.

You flood the surface with it, allow it to soak in a few hours and then wipe off any remaining oil and burnish the surface with a clean dry towel. Periodically clean the surface by using a metal blade bench scraper.

[Re: Does dough absorb wood board oil ?](#)**2002**

If I understand your dilemma correctly the dough was too extensible (stretchy) is that correct?

What can you tell me about how the dough was mixed as well as the finished dough temperature and the dough management procedure you used.

[Re: In need of guidance](#)**2003**

That's a good question, you don't! That's just one of the nicer things delivery does to your pizzas. That's one of the reasons why I never recommend delivery unless the community you're in demands delivery, then it's only through one of the contracted delivery companies.

[Re: Is delivery worth it??](#)**2004**

With a dough temperature of 19C (cold) and a room temperature of 20 to 22C (more like room temperature) you should not be getting much, if any, condensation, that being the case I would consider mixing the dough longer.

[Re: Excessive hydration?](#)**2005**

There has been much past discussion here on how to properly determine the dough absorption when using whole wheat flour.

[**Re: "Healthier" pizza?2006**](#)

What is your dough temperature and what is the fermentation room temperature? Most fermentation rooms are also humidified so they can maintain temperatures of around 90F/32.2C with 80 to 85% R.H. (relative humidity) which means that under these conditions the dough doesn't need to be covered. It's the temperature difference between the dough and the surrounding environment that can result in condensation on the dough. Also keep in mind that a dough that is not sufficiently developed will exhibit stickiness and be difficult to handle.

[**Re: Excessive hydration?2007**](#)

You've lost me here? You said you want to bulk ferment in the cooler because you don't have sufficient room in the cooler but yet you have room to inventory the balled dough in the cooler after the bulk fermentation. I'm confused. Maybe it would help if you described your work flow to me for clarity.

[**Re: bulk fermentation yeast2008**](#)

Regarding your question #2 where you ask about getting a stronger, but more elastic dough. Elasticity is a characteristic of a of a stronger dough. Are you sure you are not looking for a dough that is stronger but more extensible? This would be a dough that opens easier without tearing, and can be stretched to a greater extent without it tearing or exhibiting excessive snap-back/dough memory. If it is strength and extensibility that you are looking for changing to a stronger, higher protein content flour might be what you need, BUT keep in mind that a thinner dough does not translate to a crispier crust, just the opposite is true, so if you want to achieve a crispier center section going with a SLIGHTLY thicker center section might be the direction you need to go.

[**Re: How can I make my pies and process better -Made in Blackstone oven2009**](#)

While dough formulation is an important factor as well as fermentation and baking conditions I've found that dough absorption probably has the greatest influence on crispiness. Within reason, the higher the dough absorption, the more crispy the finished crust will be.

[**Re: Hydration Percentage, Baking Time, and Oven Temperature2010**](#)

If you can drop the finished dough temperature to 65F/20C, 0.15% compressed yeast should work OK for you. Are you planning to cut the dough directly off of the bulk dough or are you going to scale and ball it after the bulk fermentation period?

[**Re: bulk fermentation yeast2011**](#)

You're going to need to make sure you have at least 1-inch of clearance on all four sides. This is necessary to allow for airflow around the pizza and to keep the pizza far enough away from the walls of the oven to allow for a consistent bake. Rack position will be more critical than it would for a smaller diameter pizza, a slightly higher than normal rack position will probably provide the best bake.

[**Re: 18inch pizza screen in a home oven2012**](#)

Your 11.7% protein content flour should work well for a starting point.

[**Re: Achieving biscuit-like pan pizza2013**](#)

Things to keep in mind about baking deep-dish pizzas:

- 1) Allow the dough to proof in the pan for about 45-minutes, or more between fitting the dough to the pan and dressing/baking.
- 2) Use oil in the pan for a fried effect, but shortening makes it easier to fit the dough into the pan.
- 3) Most deep-dish pizzas bake better without a stone.
- 4) Use a dark colored deep-dish pan.
- 5) A 2-inch deep pan is the best as it helps to prevent scorching the toppings in view of the long bake time required. (A little physics at play here, the higher walls hold the cool, moist air over the top of the pizza to protect the toppings during baking).
- 6) Most deep-dish pizzas are going to take close to 20-minutes to bake in a home oven at 450 to 500F.
- 7) Remove the pizza from the pan IMMEDIATELY after baking.
- 8) Not knowing anything about your oven you will need to experiment with rack placement.

[Re: Cooking pizza with a thick crust?2014](#)

Neither is correct as the greatest factor involved with cooling the dough is going to be the surface exposed to the walls of the container and to a lesser extent the material the fermentation container is made from. Due to the number of variables we have never been able to accurately predict the rate of fermentation of large doughs when the dough is bulk fermented in the cooler. You will need to experimentally find the yeast level that works best in your specific case, the good news is that once you find the correct yeast level, if you always get the same finished dough temperature, and always ferment in the same container (has to be the same size dough), and always place it in the same spot in the cooler, your end result should be somewhat consistent with regard to fermentation BUT do realize that you will, in essence, have two different doughs in the fermentation container, that which is in contact with the wall of the container will be significantly different (due to more effective cooling) than that which is in the center of the dough mass where heat is not being removed very efficiently so it will show the impact of more fermentation. This characteristic of bulk fermentation in the cooler is the reason why the process never gained any popularity and is seldom used.

[Re: bulk fermentation yeast2015](#)

Warm dough + Cold refrigerated temperature + closed box = condensation.

How to prevent it? Place dough ball(s) in box/container, lightly oil said dough ball(s), leave container open (all the way open) as this will promote consistent and complete cooling of the dough ball(s). Leave container uncovered for whatever period of time is necessary for the dough to cool to 50F (internal temperature), then cover for the remainder of the cold fermentation time. To use the dough: Remove from cooler/fridge and leave the container covered until the internal dough ball temperature reaches 50 to 60F, then remove dough and begin opening into skins by your preferred method.

No condensation. This is how the stores do it.

[Re: Excessive hydration?2016](#)

Begin by moving away from the high protein flour and move more towards a lower protein bread type flour with around 10 to 11% protein content. Don't use oil, instead use shortening at 8%. Whole egg only contributes to a dry, firm crumb structure, instead, if you have to use an egg product, use only egg yolk at 5%. Remember to mix the dough JUST until it's well incorporated...5 to 6-minutes, don't

over mix it. Also remember to proof it after forming, 30 to 45-minutes should be sufficient.

[Re: Achieving biscuit-like pan pizza](#)2017

That's because the flour has had more time to hydrate. Remember that pizza doughs are NOT fully developed at the mixer so they are naturally a little tacky when balling right after mixing. If your dough is indeed "sticky" you are probably not mixing it enough. If you are using a high dough absorption you can also use an autolyze where you mix just the flour and water together (just enough to wet the flour) and allow this to rest in the mixing bowl for 30-minutes, or so, then add the remaining ingredients and mix the dough just until it takes on a smooth, satiny appearance.

[Re: Hydration Percentage, Baking Time, and Oven Temperature](#)2018

My own personal "go to" flour for making pizza is Pillsbury Bread/Bread Maker Flour which is available at most supermarkets across the U.S. It comes in at approximately 12.6% protein content, it is the same as General Mills Full Strength but in a consumer size package.

[Re: Best Flour to use at HR 65%-70%](#)2019

Sure.....I do it all the time.

For most home pizza makers the doughs size is so small so as to be equivalent to a single dough ball anyways so in my opinion, there is little or no significant difference between ball and bulk fermentation when the dough weight is less than 1-Kg. (2.2-pounds) or so. This does not mean that there isn't a difference between cold and room temperature fermentation, there's a huge difference. The only difference between "bulk" fermentation where we have a larger dough mass (under 1-Kg.) and individual dough balls weighing 225 to 500-grams is that it will take a little longer for the bulk dough to change in temperature. Additionally, the temperature gain due to heat of metabolism in the bulk dough mass is minimized if not cancelled out by its small size. Where bulk dough fermentation really makes a big difference is where we have large size doughs capable of retaining the heat generated by the yeast fermentation (about 1F per hour of fermentation). These doughs will ferment vastly differently than doughs of small size or in dough ball form.

[Re: Hydration Percentage, Baking Time, and Oven Temperature](#)2020

Next time also show a picture of the bottom, it's a lot easier to assess the bake of a pizza if you can also see the bottom.

[Re: Where to start? Starting over, that is.](#)2021

Jerry5010;

Not a problem at all, feel free to jump right on in at any time.

The main reason for using cold fermented dough at pizzerias is because of the ease and consistency of dough management. Dough which is managed through the cooler (cold fermented) is overall, much more consistent performing than dough which is managed at room temperature (remember that room temperature can be highly variable). Since temperature is the main driver of fermentation, even slight differences in the finished dough temperature can have a dramatic impact upon the dough and finished crust when projected out to several days when the dough is managed at room temperature. When the dough is managed at refrigerated temperature slight differences in finished dough temperature are not as critical as the dough will be subdivided into individual, smaller weight pieces for the

fermentation process, this allows for faster, more consistent cooling of the dough which in turn allows for improved dough consistency. Does this mean that room temperature managed dough is not as good as cold fermented dough? Absolutely not, it's just a different animal that must be managed entirely differently and I hate to say this BUT, when one considers the quality of help (workers in the food industry) today we have to take as much of the human factor out of dough processing as possible if we want to have a consistent product for our customers. I'm not sure I fully understand your last question, but if you want your dough to bake faster, look not further than your oven, if you want the dough to open easier consider increasing the dough absorption and/or increasing the dough fermentation. Along these lines it's been my experience that while most properly managed cold fermented doughs can be used after 24-hours, their "sweet spot" is at about 48-hours. Keep in mind too that the flour you're using will also influence both dough absorption and fermentation time. As a rule, the higher the protein content of the flour the higher the dough absorption will be and it will require more fermentation time to open without exhibiting excessive dough memory aka snap back. Along these same lines, have you ever wondered why high protein flours are synonymous with pizza? The answer goes back to the 1950's when pizzerias were all operating using some form of room temperature fermentation procedure which usually involved mixing the dough and just leaving it in the bowl or some other container and allowing it to ferment for the better part of the day. This dough was used for making pizzas until the dough was gone, then the lights were turned off (not a good business model, I know). In order for the dough to withstand all of the fermentation it received by this process we needed to use a high protein flour with excellent tolerance to fermentation. Flour suppliers soon recognized this and when the next person approached them and said that they too wanted to open a pizza shop the response was "well then you will need to buy a high protein flour", today though we seldom use processes like this in a commercial setting as cold fermentation dough management procedures have replaced it and with more effective dough management we have been able to reduce the need for high protein flours too, so today it is common to see flours being used in commercial pizzerias that are in the range from a low of 11.8% to about 12.8%. While many stores still use higher protein content flours (13 to 14+) we find that their pizzas can be made better with a lower protein flour, especially if they are a DELCO shop, which are popping up like mushrooms in the spring.

[Re: Hydration Percentage, Baking Time, and Oven Temperature](#) 2022

Your dough balls REALLY LOOK GOOD! :)

[Re: Problems with my dough \(not elastic: stretching is too easy, no leopard skin,...\)](#) 2023

Johnny;

If by equation you mean dough formulation, here it is.

Flour: 100% (12 to 12.8% protein content)

Salt: 1.75%

Sugar: 2% (optional)

Oil: 2%

IDY: 0.375%

Water: 62% (variable)

[Re: Tom Lehman's dough recipe](#) 2024

I like to use semolina flour to dust the dough balls in preparation for opening, most of it will come off as you open the dough into a skin.

[Re: Where to start? Starting over, that is.2025](#)

I'm in agreement with Craig.

[Re: storing stiff starter in water2026](#)

Not much to add except that when you place the dough ball into the bag pull the bag snug to the dough ball DO NOT leave an air space as this will contribute to condensation forming in the bag. The bag will expand just fine with the dough ball.

[Re: Where to start? Starting over, that is.2027](#)

Approach this in the same manner as you would eat an elephant, this is one bite at a time. If you can get it, use All Trumps flour, if not use one of the KA flours with 13 to 14% protein content. Here is a dough formula:

Flour: 100%

Salt: 2%

Water: 62%

IDY: 0.4%

Oil: 2%

Put water (70F) in mixing bowl, add salt, add flour.

Mix just until you don't see any dry flour in the bowl, then add the oil and continue mixing just until you get a smooth dough appearance.

Targeted finished dough temperature: 75 to 80F

Divide into desired weight pieces, round into balls.

Oil the dough balls, place into individual plastic bread type bags.

Twist the open end of the bag to form a pony tail and tuck it under the dough ball as you place it in the fridge.

Allow to cold ferment for at least 24-hours, 48-hours is better.

Use a rolling pin to CAREFULLY open the dough ball about 2-inches smaller than what you want.

Finish opening the dough skin by hand stretching to full diameter.

Skin is now ready for dressing and baking.

Dough weight: For a 12-inch pizza try starting with 11-ounces of dough weight.

Adjust up or down from there depending upon the thickness you're looking for.

[Re: Where to start? Starting over, that is.2028](#)

Water does play an important part in pizza dough. Hard water is good for the dough while soft water is not good for the dough as it imparts tackiness into the dough. Ditto for distilled water as well as R.O. water. The pH of the water can be critical with how the dough ferments, typically water has a pH of 6.8 to 7.2 which is fine. When the pH is higher than this the water is alkaline and will slow the start of fermentation. Water that is lower than this is said to be acid water which can be good for the dough as yeast is an acid loving micro organism so it can actually speed up the rate of fermentation slightly, BUT you will seldom find acid water coming from a municipal water supply as the acidity can erode copper pipes but more so, the lead in the joints holding it together, the dissolved lead then goes into the drinking water...not a good thing. There are cases where we want to acidify the dough slightly such as is the case when making an emergency dough, in that case some will replace 1% of the dough absorption with 1% of a white, household 50-grain strength vinegar to achieve a slight acidification, but this is all done in the mixing bowl, not out of the tap. I've written a couple of articles about this in PMQ Magazine.

[Re: Water types as a factor in pizza flavor/crust texture?2029](#)

That's about what one would expect with such a low salt level, most relate the flavor of a dough with such a low salt level to tasting "starchy". Actually, you could have just added the corrected amounts of each ingredient to the dough and reballed it for later use.

[Re: Dough SNAFU - Should I throw it out?2030](#)

Even more amazing is that your birthday is the same as my wife's!

[Re: Tom Lehman, 19622031](#)

To add to my previous post, you are going to need to make a calculated 412.5-pounds of dough, divide this by your total dough weight for a single dough and you will have the number of doughs needed to make the order. To be more precise I still need to know your total bakers% as well as flour weight.

[Re: Need 600 dough balls in one Day2032](#)

To answer your question we need some important information, what is sum of the bakers % of the ingredients used in your dough formulation and how much flour do you use to make a single dough?

[Re: Need 600 dough balls in one Day2033](#)

I think a good deal of your problem is stemming from the low % total dough absorption you're using which was further lowered when you added an additional 50-grams (5%) flour right up front. Staying with the method you're using, the changes I would make are as follows:

- 1) Suspend the IDY in a small portion of 95F water not the cool tap water. This will be much less damaging to the yeast.
- 2) Increase the dough absorption to at least 70% you will probably be able to go even higher but start at 70% and work up from there.
- 3) After hand mixing the dough in the Cambro tub, drape the tub with a piece of plastic and allow the dough to hydrate/ferment for 1-hour, or you can use an autolyze method where you mix only the flour and the water, then set it aside and allow it to hydrate for at least 30 to 60-minutes, then add the remainder of your ingredients and continue with your process.

This should help to address the stickiness and give you improved oven spring.

[Re: First post, first NP, so yeah, I have questions2034](#)

Two main things to remember about English muffins, if trying to replicate the Thomas brand, 70% dough absorption and calcium propionate at 1% for the flavor. We did a sensory panel evaluation of English muffins one time when looking at alternatives to calcium propionate as there was some speculation that it might be banned (thankfully never happened). What we found was that without the propionate our panel participants did not readily recognize the product as an English muffin. It's the calcium propionate that provides the sinus clearing effect when you smell an English muffin being toasted. It's also the reason why you never see an English muffing getting moldy too, calcium propionate is the most commonly used rope and mold inhibitor used in yeast leavened foods.

Until we got our English muffin griddle we made our English muffins using an McDonalds 3D/triple decker (Big Mac) bun pan with a snug fitting lid, The dough was placed into the lightly greased and corn meal dusted pan, allowed to proof for 15-minutes and then went to the oven at 500F. The resulting muffins were pretty close in appearance, looking a lot like hockey pucks.

[Re: First try at tartine English muffins 2035](#)

For myself personally, I'm on track to enjoying the second 40 as much or more than the first 40. Sure, I've gotten a little help along the way but that just makes things more interesting, and I really have to say that since my retirement 5-years ago my enjoyment factor went up by several notches and that's saying a lot since I really loved my job at the American Institute of Baking where I was employed for almost 50-years. So, why did I retire? To prove to myself that indeed there is a life outside of AIB.

[Re: average age?2036](#)

If it's true about what they say about life starting at 40, I guess that makes me 35. Right in line with the rest of the pack. :-D :-D :-D

[Re: average age?2037](#)

JPB;

That edge sure doesn't look flat to me! :-D

Great lookin' pizza man!

[Re: Elastic? Shrinkage?2038](#)

General Mills Full Strength flour about 12.6% protein content, essentially the same flour as the Pillsbury Bread/Bread Maker Flour available in many supermarkets.

[Re: Elastic? Shrinkage?2039](#)

Peter;

It was the one referenced in the link in reply#2.

[Re: Flat dough2040](#)

The flour that you've referenced is a durum semolina flour which is not well suited for use by itself as a pizza flour but it can be blended with a regular bread type flour at levels of up to 25% for improved chew and crispiness. The problem with durum semolina flour is that it produces a dough with EXTREMELY tough, elastic properties. This is a characteristic of the durum wheat from which this type of flour is milled, it's a different type of wheat than what is used for making regular bread type flours. I would suggest that you pick up a bag of any regular white flour suitable for making bread and give that a try, I'm betting it'll work better for you. Once you begin making pizzas more to your liking you can begin experimenting by blending in some of the Caputo and/or semolina flour that you have to see if you like the characteristics imparted by these flours when used as a blending flour.

[Re: Flat dough2041](#)

I've got a bag of Caputo Pizzeria Flour (blue bag) that I've been working with lately and one thing I can say about it is that it sure doesn't have tolerance for much more than 12 to 18-hours of total fermentation. When I evaluated it for fermentation tolerance I saw the same thing that you are seeing. The next time you make your dough schedule your fermentation sequence to keep the total dough fermentation within the 12 to 18-hour window. You don't mention anything about the finished dough temperature, this can also have a significant impact upon how much fermentation the flour/dough will exhibit.

As you were previously using a 14% protein content flour (All Trumps?) I'm assuming it was a U.S. milled flour which is very different from Italian milled flour. One of the greatest differences I'm seeing is in fermentation tolerance. U.S. milled flours are milled from wheat varieties that are bred for fermentation tolerance as one of their breeding criteria. Another is protein strength, our wheat varieties are bred to have high protein content and also high strength (elastic) characteristics.

Italian flours are designed to have a shorter fermentation tolerance and a significantly more extensible gluten characteristic. If your pizzas were OK with the 14% protein content flour but the dough was just too difficult to open a better approach might have been to just change to a lower protein content flour, possibly something in the 10.8 to 12% protein content range.

[Re: Flat dough?2042](#)

JPB;

That sounds as if you might be over extending the dough (opening it too much). The dough in the rim shouldn't get there by shrinking it back onto the peel, it's formed at the time of opening the dough ball into a skin by keeping your fingers away from the edge during the opening process. If you want to accentuate the rim on the finished pizza the correct way to achieve it is to use a bit more dough. I'd suggest trying 2-ounces more dough weight the next time and just opening the dough to fit the peel, if done right the center section should be like a normal pizza for you and the extra dough will end up more so at the edge where it will contribute to a more pronounced rim on the finished crust.

[Re: Elastic? Shrinkage?2043](#)

Q.J. is spot on with his time and temperature recommendations, couldn't have said it better myself. :)

[Re: Hydration Percentage, Baking Time, and Oven Temperature?2044](#)

If the skin is shrinking significantly during transfer to the peel it was most likely due to insufficient fermentation. Much of this can be either reduced or eliminated by placing the opened skin directly onto the peel and then dressing the skin on the peel. If this is the way you are presently handling the skins the problem is almost guaranteed to be due to insufficient fermentation. If it was due to excessive fermentation which results in a "bucky" dough condition the dough would have been much more difficult to open from a dough ball.

[Re: Elastic? Shrinkage?2045](#)

The only off aromas that I'm familiar with in baked products are best described as over ripe cantaloupe, acetone/nail polish remover both of which are due to bacillus mesentericus/bacillus subtilis aka "rope", but this are found in the finished/baked product not in the dough. Rope is due to a spore forming bacteria which not only survives baking temperatures it is also more active after being exposed to baking temperatures. Beside its characteristic aroma, it is also identified by a slight brown discoloration in the crumb which when touched is very sticky and forms a thread (rope) when the finger is pulled away. Rope is insidious and the #1 fear of any facility processing baked goods.

[Re: Isoamyl acetate in dough?2046](#)

From the looks of it I'm guessing that it's nothing more than IDY with an added inactive white sour for flavor. We have been doing this for decades in the wholesale baking industry as well as in some segments of the frozen dough and frozen pizza industries. Red Star manufactures both of these items so it would only be natural that they combine them.

[Re: Instant Sourdough Yeast?2047](#)

Both brewers and bakers yeast can be used in making dough. There is little, if any, significant difference in the finished product when either yeast is used. The only main difference between the two yeasts is in their tolerance to alcohol, brewers

yeast has about a 1% higher tolerance to alcohol than bakers yeast.

[Re: Nonfat milk powder vs Full Cream milk powder vs Oil vs High hydration](#) 2048

Here's a dough formula for puff pastry in bakers percent so you can adjust the amount to any size dough you wish to make.

Flour: (pastry or bread type flour may be used) 100%

Salt: 2.5%

Nonfat dry milk: 2% (variable to adjust crust color).

Water: (ice cold) 35%

Shortening: 20%

Roll-In : 60% (this is a high temperature plastic fat containing water) This portion of the fat is added ONLY as a roll-in fat.

Note:

While a commercial Roll-In fat designed specifically for puff pastry application works best butter or margarine can also be used. Danish butter works better than other types of butter due to its unique plasticity at low temperature. DO NOT USE A PLAIN ALL PURPOSE SHORTENING FOR THE ROLL-IN AS IT DOESN'T CONTAIN THE NECESSARY WATER NEEDED FOR EXPANSION (LEAVENING) OF THE DOUGH.

Add flour, salt and NFDM to the bowl first, then add the shortening in chunks, using a pastry knife mixing attachment cut the fat into the flour, then add the water in a steady stream while continuing to mix at low speed. When a "shaggy" dough consistency is achieved change to a dough hook/reverse spiral dough arm and mix at low speed JUST until the dough begins to take on a smooth appearance.

Remove the dough from the mixer, cut into approximately 3Kg. pieces, pin out to fit onto an 18 X 26 lightly floured sheet pan, cover with plastic and refrigerate about 30-minutes. Process all of the dough in this manner. Remove a pan of dough from the cooler and begin sheeting it to about 1/2-inch / 12.5 mm thickness, add roll-in fat to 2/3 of the dough and give the dough a 3-fold, pin out to fit the sheet pan again and refrigerate for 20 to 30-minutes (time will be variable), roll the dough out again to 1/2-inch / 12.5 mm thickness and give the dough a 4-fold. Roll out again to fit the pan and refrigerate. NOTE: You will need to experiment with the number of folds to give the dough to determine the type of flake you want. Some will stop at just one 4-fold while others will go to one additional 4-fold followed by a 3-fold.

The idea is to keep the dough cold as you are rolling/sheeting it as this will prevent the roll-in fat from being incorporated INTO the dough which will destroy the flake properties of the finished pastry.

When sheeting the dough for cutting/shaping reduce the dough to about 1/4-inch / 6mm thickness.

Puff pastry is typically baked at about 400F/205C.

Things to keep in mind:

As you continue to give the dough more folds you may need to leave the dough in the cooler longer for it to sufficiently relax between folds. The dough will be easier to work with if you allow the dough to relax in the cooler for a few hours before sheeting the dough to its final thickness for shaping.

Depending upon the finished color you are looking for and the strength of the flour you are using you may want to consider adding 1% vinegar or lemon juice to the water. This will help to relax the dough as well as reduce the crust color development during baking.

NOTE: After you have divided the dough into 3kg. pieces, be sure to divide the roll-in fat into the same number of pieces as you will need to use one portion of the roll-in to one portion (3Kg) of the dough.

[Re: Anyone got the recipe for "puff pastry dough"](#)**2049**

Very few pizzerias use NFDM or dry milk derivatives due to their extraordinarily high cost v/s benefit. The benefit to be gained is the introduction of lactose sugar aka milk sugar which helps to induce crust color development just as any other sugar would. While there would be some potential dough strengthening due to the calcium ion effect this would be important only in bread production as pizza doughs are not based upon full gluten development as bread doughs are. It is true that the addition of oil at high levels too soon in the mixing process can/will interfere with gluten development this is easily addressed by adding the oil later in the mixing process as we do in my delayed oil addition mixing procedure. It is indeed the addition of water to the dough (increased dough absorption) that is responsible for developing crispiness in the finished crust but only if the crust is baked properly to begin with. This means that you will want to experiment with balancing baking time and temperature with sugar level to allow the crust to be baked for optimum oven spring and crispiness without excessive crust color development. A number of factors will come into play when doing this, for example type and weight of pan, color of pan, type of oven, gas or electric oven, baking surface, oil or shortening in the pan and of course dough formulation. Most of these will cancel out as a constant, but if you change any thing it will become a variable so just record it and track the changes to help you keep track of what's happening.

[Re: Nonfat milk powder vs Full Cream milk powder vs Oil vs High hydration](#)**2050**

Not so strange here, we're all here to help you, more like a family.

Are you in Watertown, South Dakota?

[Re: Dough recipe questions](#)**2051**

The dough ball has a smooth skin with no rips or tears, looks great to me.

What was the finished dough temperature?

[Re: Pizza rim came out flat](#)**2052**

If the 24-ounce dough balls are being used for the 16-inch deep-dish pizza your dough loading factor is 0.1194 so 0.1194×113 gives you a suggested scaling weight of 13.5-ounces for the 12-inch deep-dish pizza as opposed to the 12-ounces you're presently using.

If you would like to discuss these issues with me please feel free to call me at 785-537-1037, I think I can get you pointed in the right direction with a short phone call.

[Re: Dough recipe questions](#)**2053**

I make mostly a New York style pizza, and I typically use 65 to 67% dough absorption. My "go to" baking temperature is 500 to 550F. The Marsal deck ovens are the deck ovens of preference for me, they have a deck that is thicker than most deck ovens and they hold heat and retain baking temperature very well. As for the oven, it all depends upon what style of pizza you're making. For N.Y. style pizza the Marsals are hard to beat in both performance and price.

[Re: Hydration Percentage, Baking Time, and Oven Temperature](#)**2054**

The whole objective in baling the dough is best summarized by one word....consistency. If the dough is balled sometimes tight and sometimes lose there can be considerable variation in the way the dough ball expends during fermentation as well as the way it reacts during opening. One thing I can say about mechanical rounders is they are consistent in the way they round the dough balls. If you want the dough balls rounded tighter you just pass them through the rounder twice aka double rounding.

[**Re: Dough rounder BALLMATIC 1000**](#)**2055**

After I responded I Googled them and saw that they are made in Italy. I don't have any experience with that brand, but the Round-O Matic is a great performer and very fast too. As there are only 4 parts to remove for cleaning there isn't much to go wrong. Cost is about \$9,000.00 depending upon specific model. At \$3,300.00 this would appear to be a pretty good buy, maybe if you also post in the PMQ Think Tank you might be able to find someone who has one and can comment on their experience with it.

[**Re: Dough rounder BALLMATIC 1000**](#)**2056**

Where is it made? Assuming China?

[**Re: Dough rounder BALLMATIC 1000**](#)**2057**

That's a knock-off of the AM-Manufacturing Round-O-Matic R-900 series dough ball rounder.

I can't speak for the one you have referenced but the Round-O-Matic is a great little dough ball rounder as long as the dough absorption isn't much above the 66 to 68% range (American type flour) and the dough isn't overly soft/extensible. Only four parts to clean, super easy.

[**Re: Dough rounder BALLMATIC 1000**](#)**2058**

Actually, you're not making a poolish, instead you are making a "pre-ferment" aka "brew". This is likely contributing to the over fermentation condition. Try making your poolish without added yeast, you only need to leave the poolish hydrate for 1 to 3-hours, so even go shorter than that. I seldom ever use a poolish unless I'm working with a high absorption dough (70% and above). As to total fermentation time 48-hours on the dough is a good target to shoot for, once you have mastered that, you can go for 72 then 96-hours if you wish.

Pizzerias, unless they are making deep-dish type pizzas don't proof their dough very often, they get all of their fermentation in the walk-in cooler. A typical dough management procedure for a pizzeria is:

Mix (75 to 80F)

Immediately scale and ball.

Box and oil dough balls

Cross-stack in the cooler for 2 to 3-hours (until dough reaches 50 to 55F)

Down-stack

Cold ferment for 24 to 48-hours (72-hours is typically max.)

Remove from cooler (keep covered) and allow to warm to 50F. (internal ball temperature)

Begin opening balls into skins (dough will be good to use for a 3-hour period of time)

If you would like to have a copy of the procedure with all of the details send me an email at <thedoughdoctor@hotmail.com> requesting a copy of my Dough Management Procedure.

[Re: Stiff dough that resists opening](#)**2059**

Your problem with stretching the dough wasn't due to lack of gluten development during mixing, biochemical gluten development takes care of the gluten development for you when you ferment the dough for 24 hours or more, instead, the problem was most likely due to not allowing the dough to warm sufficiently before opening it into a skin. In pizzerias we use 50F as the target temperature but in home use where you are only making a few pizzas at most many people opt to go with 60F. Anything above that can result in a gassy dough that can be difficult to work with and open into a skin.

[Re: dough temperature question](#)**2060**

If your dough is being properly managed it should not need to be re-balled. I only re-ball if the dough is over fermented and then you will need to allow the dough ball to rest again for a sufficiently long time for it to relax sufficiently to be easily opened, this can and usually does require several hours.

[Re: Pizza rim came out flat](#)**2061**

If you can get some VWG use it to increase the protein content of your flour to something in the 12.5 to 13% protein range. How much VWG to use?

Using the 11% protein flour you have available to you, subtract 11 from 13 = 2 (this means that you will need to increase the protein content of the 11% protein flour by 2%. Divide 2 by 0.6 = 3.3 (this means that you will need to replace 3.3% of the 11% protein content flour with 3.3% VWG.

The rule is: Determine how much you want to increase the protein content by, then divide that number by 0.6, the answer will be the % VWG that will need to be used to increase the protein content of the flour to the desired level. BUT remember that for each % VWG that you add you MUST increase the dough absorption by an additional 2%, so in the above example where we found that we need to add 3.3% VWG you will also need to increase the dough absorption by an additional 6.6% to adjust for the absorption properties of the VWG. To add the VWG just lightly blend/whisk it into the flour.

[Re: Pizza rim came out flat](#)**2062**

Frozen pizza dough is made by some of the major frozen dough manufacturers here in the U.S. (Drayton and Rich's) to name but two. The market is pretty significant in size too. Users include small pizza shops, restaurants, bars, snack food facilities, as well as home use applications. As for cost, the cost of pizza dough in the U.S. is around \$0.25 to \$0.35 per pound but with the cost to manufacture the dough included (2.5 X actual ingredient cost) the cost rises to about \$0.55 to \$0.66 per pound. Frozen dough will typically sell for about \$1.00 to \$1.25 per pound. The individual dough ball cost will less depending upon the weight of the dough ball but an average dough ball will sell for \$0.75 to \$1.00 each. How high have I seen frozen dough being sold for? \$1.50 to \$2.00 per pound is about the highest I've seen it go for in some of the more remote areas of the country.

[Re: Is there a need for frozen pizza dough?](#)**2063**

Yael;

No truer words were ever spoken. ^^^

When doing research we learn from both our successes and our failures. I've learned a lot from both ends of that stick.

One thing that I might add regarding baking low absorption pizza doughs is to bake them at a lower temperature than high absorption doughs. Low absorption

(50% and less) doughs typically bake better at around 500F/260C.

[Re: Help! Accidentally made 50% hydration dough! What now?2064](#)

What is the Lintner Value of your malt?

[Re: Diastatic malt powder and autolyse2065](#)

From your description I'm guessing that your dough is being over fermented. You might try this; Reduce the CF time to 6-hours and then follow your usual procedure and let us know if you see any improvement. I can say for sure that your dough is not being over mixed.

It's hard to say much more than that without knowing your dough formula and finished dough temperature.

[Re: Stiff dough that resists opening2066](#)

Your dough temperature was quite cold and the water temperature in which you suspended the IDY in was WWAAYY too cold and in all probability resulted in some damage to the yeast. IDY should never be suspended in water colder than 95F/35C.

[Re: Pizza rim came out flat2067](#)

Peter;

Nothing like exploring a path never traveled.

[Re: Help! Accidentally made 50% hydration dough! What now?2068](#)

Peter;

He is still going to get good fermentation in 24-hours. I don't know what the fermentation tolerance of his flour is so I'm hesitant to say that a longer fermentation time would be beneficial. Besides, there's nothing wrong with making a thin crispy crust once in a while, remember there have been some pretty significant products made as a result of a mistake.....bagels for one.

[Re: Help! Accidentally made 50% hydration dough! What now?2069](#)

With 3% salt and 2.8% sugar 0.3% IDY was probably not enough yeast. It would have been better to use something closer to 0.5% IDY. Additionally, what was the water temperature that you suspended the IDY in? That's important to know here along with the finished dough temperature.

[Re: Pizza rim came out flat2070](#)

Congratulations! You're going to be making some thin crispy pizzas! :-D

Just handle the dough in your usual manner and when it comes time to open the dough balls into skins use a rolling or pastry pin and dusting flour as needed. Open to about 1.5 to 2-mm thickness, dock the dough skin with a dough docker if you have one or use a new lead pencil for a docker. Oil the eraser end and use this to dock the dough skin....a bit tedious but it works in a pinch. Don't use a fork as that is NOT docking. If necessary, trim the skin to the exact diameter you want. dress to the order and bake at 500 to 550F/260 to 288C.

Let us know how it turns out. You might like it. ;D

[Re: Help! Accidentally made 50% hydration dough! What now?2071](#)

Thank you! I'll toast to that! :pizza: ;D

[Re: A Frivolous Question For The Dough Doctor2072](#)

Rolls;

Occasionally I get those feelings but then I'm reminded that there are so many new

things happening with pizza and so many people in need of assistance that I quickly put those thoughts to rest and jump right back into the pool and seldom ever look back or have any regrets. I'm always up to trying one more slice because I'm afraid I'll miss something if I don't.

As for my favorite pizza, I'd have to say it's AJ's New York Pizzeria, Manhattan, Kansas. I have to admit that I'm partial to it because my DNA is all over the pizza as well as the pizza concept, so if I don't like it I only have myself to blame. I have two favorite pizza chasers, if I'm driving it's a large, cold root beer. If I'm not driving it'll be a tall Guiness Stout ;D

I've always considered it an honor to be able to participate in sites like this as well as the PMQ Think Tank and to be asked to participate in Pizza Expo (don't know how many years I've done P.E. but it's been most of them).

In the end, my own personal rewards come when someone writes me or approaches me and starts the conversation by saying "You probably don't remember me but your advice helped my get my store off the ground".....what more can one ask for?

[Re: A Frivolous Question For The Dough Doctor2073](#)

While indeed, there are a number of different ways to formulate a starter into the dough, in the end the only one that counts is the one that works best for you. Dough formulas are the same way as well as dough management procedures (there are soooooo many!), some might be better than others for any number of reasons, but in the end the best one is the one that works best for YOU.

[Re: Gooey Sticky Dough at 64% w/Starter2074](#)

Working in a little fresh flour into the dough will help to restrengthen the dough which is most likely being weakened by prolonged exposure to the high acidity of your sourdough starter.

[Re: How to fix overfemented retarded dough balls2075](#)

You can even make a pretty decent pizza using just the cook top (burners) and a covered frying pan, similar to the way camp pizza is made.

[Re: is that good or bad if i making pizza by Microwave2076](#)

5F could put you into the 40 to 45F or higher range depending upon at what temperature you keep your fridge set at. You say you used colder water temperature, how much colder? How much did it lower/reduce the finished dough temperature? If your dough didn't seem to want to stop/slow down with regard to the fermentation rate I'm guessing that your fridge got into the mid to high 40's and couldn't cool the dough sufficiently so as the dough continued to ferment it continued to increase in temperature due to heat of metabolism which continued to drive fermentation at an increasingly faster rate.

[Re: Low IDY = D.O.A.2077](#)

Rolls;

Here is the dough formula in grams based on 300-grams of total flour weight.

Flour: 100% 300-grams

Water: 62% 163.5-grams ($186 - 22.5 = 163.5$) Test: $163.5 + 22.5 = 186$ 186 divided by 300 X 100 = 62 (62%)

Starter: 15% 45-grams (22.5-grams flour + 22.5-grams water)

Oil: 7% 21-grams

Salt: 3% 9-grams

Malt: 0.25% 0.75-grams

[Re: Gooey Sticky Dough at 64% w/Starter](#)**2078**

With the typical soft dough condition with the Caputo flours and relatively high dough absorption when combined with the high baking temperature you get rapid expansion during the oven spring part of the baking process which results in the characteristic open, porous crumb structure. If the flour was malted you would get too much crust color on the bottom of the crust during baking...hence, they don't malt the flour.

[Re: Is Caputo 00 just hype or am I missing something?](#)**2079**

Total flour weight (in the dough, not to include that which is in the starter) is indeed the best way to calculate the weight of the starter to be used. Think of it as just another ingredient. The reason why I don't like to use total dough weight as the basis for calculating the weight of the starter to be used is because if your dough happens to be made using a high dough absorption percent it will result in a greater weight for the starter, and a high absorption dough may not be able to tolerate the weakening affect of the starter where as if everything is based on the actual dough flour weight this will not be a problem.

[Re: Gooey Sticky Dough at 64% w/Starter](#)**2080**

Hopefully you will be using a "dough formula" based on actual ingredient weights as opposed to a "dough recipe" based on volumetric portions as formulas are much more accurate and reproducible plus they have the added advantage of allowing you to easily manipulate the size of the dough you want to make. :-D

As for using dough formulas from this or any other public site, everything here is in what is referred to as "public domain" so you're free to use it as you wish. For additional help you can also go to my web site at <www.doughdoctor.com> for help with dough mixing and management procedures.

[Re: Question about using recipes?](#)**2081**

With all of the flour in the bowl you don't need to worry about the salt and yeast playing well together....they'll be just fine. Your procedure already has me worn out, but remember that I'm a firm believer in the KISS principle, so take it with a grain of salt. Yes, I think you should still take a look at a procedure along the lines of which I proposed, I think it will work well for you.

Don't sweat the coffee thing. Sometimes I'm up until the wee morning hours conversing with International clients, and just before I shut down for the night I come back here to answer any new questions, probably not the best thing to do as my brains are pretty well scrambled and it sometimes shows in my responses as many here can attest to...heck! I have even managed to spell my own name wrong!!! :-D

[Re: difference between IDY and ADY \(glutenboy method vs what Gemignani says\)](#)**2082**

The "00" flours are not malted so unless you can bake the pizzas at or above 750F you're wasting your money on it. These flours also have a short fermentation tolerance so, depending upon which one you're looking at think in terms of 12 or 24-hours total fermentation time. Because the flour is made from soft wheat varieties the resulting dough is very extensible which can be a blessing or a hindrance depending upon your skills at opening the dough into a skin. There are a handful of flour mills in the U.S. making "00" type flours but they are really not all that common or popular when you look at the big picture of flour as it pertains to use in making pizza....think of it as a specialty flour. Most people do a pretty

respectable job of making decent Neapolitan style pizzas using some of the A.P. and bread type flours.

[Re: Is Caputo 00 just hype or am I missing something?2083](#)

The main difference between ADY and IDY is that the IDY doesn't need to be suspended in water and allowed to activate prior to addition to the dough. That's right, it is added in the dry form. The best way to add it is to just place it right on top of the flour, the hook/dough agitator will disperse it in the flour for you. The reference to "instant" in IDY does not have anything to do with activity, it is a reference to the rate of hydration of the yeast. Due to the differences in moisture content between ADY and IDY you will need to use less IDY to achieve the same fermentation as ADY. On average, you will need to use 25% less IDY than ADY to achieve similar fermentation rates.

There are some cases where the IDY must be suspended in water prior to addition, such as when making a totally hand mixed dough. In this case the IDY is only suspended in 95F water (the temperature is CRITICAL, use a thermometer) it does not need to be activated like ADY. Another case where the IDY needs to be pre-suspended is when the total machine mixing time is less than 5-minutes such as is the case for cracker type crusts as well as use of VCM and similar types of mixers. I'm not sure I understand your mixing process. Put water in mixing bowl, add half of the "dough" do you mean dough ingredients? Let it sit for 15-minutes (without mixing?) I see that you are also adding the salt last, there is really no need to do this as it can be added in the second part of the addition. Something you might want to explore is putting the water in the bowl, adding the yeast, malt (don't know why if your flour is already malted), all of the flour and the salt on top of the flour, mix to incorporate, then proceed as you presently do. Makes for a much more straight forward process.

[Re: difference between IDY and ADY \(glutenboy method vs what Gemignani says\)2084](#)

Check to see if you can find Pillsbury Bread/Bread Maker flour. This is the same as Pillsbury Superlative flour as it comes in at about 12.4% protein content. I've personally used it to make all types of pizzas quite successfully. I like to refer to it as my "all-purpose" pizza flour (not to be confused with All-Purpose flour). With your "J" hook I'm betting that you are not getting sufficient mixing at low speed prior to adding the oil. Try mixing in low speed for 2-minutes and then going to a higher speed, where you can visually see the dough getting a better mixing action for at least 2 more minutes before adding the oil. The oil does not have a whetting effect upon the flour, it only has a lubricating effect. Since your starter is based on 50/50 flour+water, when adding 15% starter you will need to reduce the added dough water by the amount of water contained in the starter. You show a total dough absorption of 64% (this should include both added water and the water coming from the addition of 15% starter. If you are not doing this your absorption is actually $64\% + 7.5\% = 71.5\%$ and on top of that you are adding 7% oil which further loosens the dough. The oil should not cause a sticky dough but instead only a soft, extensible dough condition. Remember, the percentage shown as the total dough absorption is based on the TOTAL amount of water going into the dough divided by the total flour weight (NOT to include the flour in the starter). To adjust for the lubricating effect of the oil and to improve dough handling properties you might want to reduce the total dough absorption to 59 to 60%.

The oil itself is not going to be directly responsible for a sticky dough condition unless one of two things are happening; 1) The oil is not added AFTER the flour has had a chance to hydrate in the mixing bowl prior to the oil addition. 2) Since the oil

is a lubricant it will lubricate the dough during mixing, thus reducing actual gluten development so a longer mixing time will be required than a dough made with a much lower oil level. It is not uncommon to see dough mixing times (with a reverse spiral dough arm) run out to 12 to 15-minutes because of this lubricating effect. With a straight "J" hook it is impossible for me to say how long the mixing time might be without actually watching the dough being mixed, but you can bet it will be in the 10 to 15-minute bracket. With that said, if the dough is clinging to the hook or climbing up the hook (both common problems with the "J" hook) it might never get properly developed unless you can mix the dough at a sufficiently high speed so the dough gets flung off of the "J" hook.

Just to make sure there isn't an issue with ingredient amounts can you please share your dough formula showing the ingredient amounts in both bakers percent (I know you have already done that) and also in the weight measurements you are using.

[Re: Gooey Sticky Dough at 64% w/Starter](#)**2085**

When it comes to impact upon fermentation the yeast doesn't care when the salt is added, it's all the same. As to the impact of salt on dough mixing, you can develop gluten faster without salt in the dough. In a commercial bread or bun bakery the mixing time is reduced by about 2-minutes when the delayed salt addition mixing method is employed (this is when the salt is added to the dough about 4-minutes before the end of the mixing time).

In the mixing of pizza doughs where there is no need or desire to fully develop the gluten the delayed salt addition mixing method is seldom ever used. When making commercial frozen pizza dough, that's a different story, now the salt is almost always delayed as full gluten development is desired plus there doughs are mixed very cold making the doughs quite tough in the mixer, by delaying the salt addition in this case the gluten is developed faster and the dough is not quite as tough so it's overall easier on the mixer too, when you consider that the mixer carries a price tag of the better part of \$100,00.00 this is an important consideration.

[Re: adding salt too early??](#)**2086**

Easiest way is to put the water in the mixing bowl first, then add salt and sugar (if used) no need to stir. Add the flour and the IDY (dry) or ADY (suspended/activated) and begin mixing. As soon as the flour is whetted (dry flour is no longer visible in the bottom of the bowl, add the oil and continue mixing. NOTE: If compressed yeast (CY) is used just crumble it right on top of the flour and begin mixing. As you can see, I'm a firm believer in the KISS principle. Besides, it works just fine.

[Re: adding salt too early??](#)**2087**

While I don't have a hard and fast answer to the problem, lets begin by saying that your starter is the "great unknown" since we don't have a clue as to what we're culturing or how much and specifically what acids are being formed. My recommendation is to reduce the amount of starter being added by 75%, if the dough looks better, then you can begin increasing the amount gradually until you find the optimum addition level for the flour that you're using.

Your dough mixing procedure might also have something to do with it too, how are you mixing your dough?

[Re: Gooey Sticky Dough at 64% w/Starter](#)**2088**

If you treat your peel with a little mineral oil it will help to prevent the grain from raising every time you get something wet on it.

[Re: Looking after a wooden peel](#)**2089**

Those mixers are OK for bread type doughs but if your pizza doughs are going to be higher absorption than a bread dough (above 68%) that mixer will struggle to give you a consistent dough. Where are you located?

[Re: Sideways spiral mixer? What is it? Any good?2090](#)

I'm pretty sure your sticky/tacky dough is due to under mixing. You need to mix the dough just until it takes on a smooth, satiny appearance, as soon as it reaches that point the stickiness will disappear.

Also, are you using the delayed oil addition mixing method? If not you really should be with that amount of oil.

Delayed oil addition mixing method: Put water in mixing bowl, then add activated ADY suspension followed by the flour, add salt and sugar, mix JUST until the flour is whetted, add the oil and continue mixing until you achieve the described smooth dough appearance.

[Re: Dough Hydration2091](#)

You can use just about any type of sugar in your dough but at the typical use levels used in pizza dough (1 to 3%) it really won't impact flavor and it will have little, if any impact upon crumb color. Sugar is mostly all about crust color....the more you use, the darker the crust color assuming all things equal. Sugar also provides nutrient for the yeast to feed upon (exception being lactose).

If sugar is not used in the dough formula the baking is usually done at a higher temperature and sometimes for a longer time. If the flour is malted or treated with amylose enzyme you can easily delete the sugar if you wish but if it is not malted or treated with amylose you will need sugar to help develop crust color unless you are baking at 750F or higher. Sugar is also needed to support fermentation if you plan to ferment for much more than overnight with an unmalted flour.

If you opt not to use sugar in the dough formulation no changes need to be made to mixing but not comments above regarding fermentation and baking.

[Re: Sugar in the dough?2092](#)

Try doing this;

Form your dough balls and lightly oil them.

Place into individual plastic Food Bags (like bread bags) Don't use Zip-Lock Bags.

Twist the open end to form a ponytail and tuck it under the dough ball as you place the ball into the fridge.

To use the dough after 24 to 48-hours cold fermentation remove from fridge, allow the dough ball to warm to 50 to 60F.

Roll the bag down around the dough ball and invert allowing the dough ball to fall onto a floured surface.

Flour the dough ball and open into a skin by your preferred manner.

We have had some recent discussion on this procedure here in other posts.

[Re: Dry dough tough to stretch2093](#)

It's impossible to answer your question without first knowing your dough formulation, type of flour being used, and how it's being mixed (type of mixer, mixing speed, mixing time and finished dough temperature) as well as any treatment on the flour such as bleached, enriched, bromated, amylase added, malted, etc. the bag will provide this information. With this information we can make a more educated assessment as to what might be happening.

[Re: Dough Hydration2094](#)

That's roughly equivalent to 7, 12" pizzas. Or put another way, eating one 12-inch pizza every 6.5-minutes for 45-minutes.....BURP!

[Re: Think you can finish a 32" pie in under 45 minutes?2095](#)

Sounds like it might be over fermented. I usually just turn the fermented dough ball out of the bag after allowing it to set at room temperature for about an hour, but when making pan pizzas it is usually easier to just place it directly into the pan and immediately fit the dough to the pan, then lightly cover the pan and set aside to proof for 60 to 120-minutes, depending upon formulation, room temperature and how thick you want the crust to be.

[Re: dough question2096](#)

John;

How many smaller containers do you have on the top of your prep table? Usually we will only have a few of the lesser used ingredients or larger refill containers of the most often used ingredients stored in the reach-in under the prep table. If you have at least 20 ingredients/toppings stored under the table you might be trying to do too much topping wise. just a thought.

[Re: How to organise ingredients2097](#)

For dough storage in a limited space it's hard to beat plastic bagging the dough balls. After forming the dough balls just wipe them with oil and place into individual plastic bags (I use to use recycled bread bags) but just about any reasonably sized bag will work. After placing the oiled dough ball into the bag, pull the bag snug but not tight to the dough ball, twist the open end to form a pony tail and tuck the pony tail under the dough ball as you place it onto a flat surface. This is important as it allows the bag to "burp" and to expand with the dough ball without ripping or splitting out the seams. To use the dough just pull the bag down around the dough ball and invert the bag allowing the dough ball to fall onto a floured surface, it's then ready for immediate opening into a skin by your preferred method. If you review some of the recent posts you will see some recent discussion on this topic along with a photo of the fermented dough in a bag ready for use.

[Re: Dough proofing box for home use2098](#)

That looks about right. ^^^

[Re: dough question2099](#)

First question out of the box, at what temperature are you going to bake your pizzas at?

[Re: Wrong flour2100](#)

While I am not an advocate of cooked sauce this is one of those cases where a cooked sauce is going to be better than an uncooked sauce.

[Re: Freezing sauce2101](#)

You might also go to my web site at www.doughdoctor.com and take a look at the video on making dough that I have posted, it shows the dough ball being opened into a skin which might help.

[Re: Large air bubbles in crust2102](#)

As you're opening the skin keep your fingers closer to the edge of the skin.

[Re: Large air bubbles in crust2103](#)

Nope, not at all, the crust is insoluble. I wouldn't through the dough out though, just go ahead and use it and take corrective measures the next time. All it's going to do is become the nucleus for some larger holes in the crumb.

In a way, that's how they get the dominant bubbles in a soda cracker.

[Re: dough question2104](#)

That's how we used to test the dough to make sure yeast was added when I worked in a large wholesale bakery, I'm like Craig..... I sure wouldn't call it a "technique", but everybody's got their "THING" when it comes to pizza. :-D

[Re: Interesting prefermentation technique for short fermentations2105](#)

Lookin' good! :chef:

[Re: Dough balls have rips in them??2106](#)

Just fro the looks of it I'd say it is due to your opening technique.

[Re: Large air bubbles in crust2107](#)

Without knowing just how you are handling the dough it's hard to say exactly what's happening but going on the premise that you didn't cover the dough in the fridge I'll make a "SWAG" that what you are seeing is just common drying or a slight crusting of the dough surface. What we typically do is to lightly oil the dough ball as you did but then after 2 to 3-hours cover the container to prevent the drying that you are observing. The oil on the dough ball only serves to keep it from crusting during the limited cross-stack/open time, after that it still needs to be covered for the duration of the time in the fridge. An alternative to this is to lightly oil the dough ball and place it into a plastic bag (like a bread bag), twist the open end into a pony tail to close and then tuck the pony tail under the dough ball as you place it into the fridge. By this method no further handling is needed until you're ready to use the dough.

The crust that has formed will no longer turn into anything resembling the un-crusted dough but if it is still pliable and not "hard crusty" you can go ahead and work it back into the rest of the dough.

[Re: dough question2108](#)

Uncle914;

Unless you are baking at 750F or higher forget about the Caputo flour as it really isn't intended for home use. If you do get some you will want to get some diastatic (enzyme active) malt 20 degree L. value. Then include 0.25 to 0.5% of the malt in your dough formulation. Without the malt you will have poor crust color development and the yeast may run out of nutrient to feed upon during the fermentation period leading to other issues.

Here's the bitter truth about bulk fermenting the dough in small quantities as you are. First, when we think of the difference between mixing, scaling/balling and cold fermenting v/s mixing, bulk cold bulk fermenting, scaling/balling and cold fermenting again the differences most often cited are based on the differences which are due to the dough in significantly larger quantities, at least 5 Kg. (11-pounds) total dough weight. When you bulk ferment 1.5 to 2-pounds of total dough weight the dough is too small to retain much, if any, of the heat generated due to heat of metabolism so the dough performs/ferments just as a large dough ball would, hence.....not much, if any advantage. From research that we did many years ago we found that a 2-pound dough ball (call it a "bulk" dough in this case, will experience only about 1.5 to 2-hours more fermentation in any given period of time than a 12-ounce dough ball in the same period of time under the same dough

management procedure.

To do some meaningful testing I would suggest getting a good scale capable of weighing in grams (I use a KD-8000 / about \$40.00) and a dial or electronic thermometer for measuring dough temperature (\$4.00 to \$12.00). With these tools you will be able to change your "recipe" into a "formula" based on weight measures rather than volumetric portions which will allow you to work in bakers percent which, in turn, will allow you to effectively make accurate changes to your dough formulation and manipulate your dough management procedure and accurately tracking your results to making better or different pizzas.

[Re: When to divide bulk cold fermented dough](#)**2109**

Due to their acidity apples are pretty resistant to mold, at least much more than bread or pizza crust.

[Re: Anyone tried this for storage?](#)**2110**

Samuelgross;

What type of yeast are you using? Malt/diastatic or non-diastatic? Degree L.? Whey, bakery grade or non-bakery grade? Lactic acid, dry or liquid? Concentration? Ditto for the acetic acid. What is the pH of the dough after mixing? Are you interchangeably hand tossing and sheeting? If not which forming method do you use to open the dough balls into skins?

Normally when you proof the dough/skins on a screen the dough tends to flow into the screen openings and then expand during baking to effectively lock the dough to the pan after baking, this can be compounded when you over wrap the skins on the screen which further pushes the dough into the screen openings. One effective solution to this is to simply turn the proofed skin off of the screen on which it was proofed and onto another screen so the screen marks are now oriented to the top of the pizza where they can be covered by sauce and cheese, plus, since they are on the top they will also tend to come out or lessen during the oven spring phase of baking.

I should also point out that Mondako flour is shown to be at 12% protein content and 475F with a 4-minute and 55-second baking time seems rather low temperature and short baking time for a highly acidified dough....usually I see a temperature of 500 to 510F with a baking time of 6.5 to 6.75-minutes, but then I don't know what your top finger configuration is or how many top fingers your oven has so I can easily be wrong on that for your specific oven. In any case a pH of the dough would give the necessary direction.

I'm sure with a little work we can work this out.

[Re: Obtaining a fluffy but crunchy crust with my lactic/acetic acid infused dough](#)**2111**

We've never seen any affect upon the crust due to oil addition to the dough unless as otherwise previously stated.

[Re: Does oil affect crust color?](#)**2112**

Was able to help out a large group of new operators at Pizza Expo too, one session (scheduled for 4-hours went to 6-hours) and the other session scheduled for 1-hour went to nearly 7-hours. It was time well spent. Even had a chance to meet a few of our followers from here too.

[Re: wet doughs](#)**2113**

I'm temporarily back but not too much to add as the addition of oil to the dough at "normal" levels 5% and less just doesn't have a significant impact upon crust color

characteristics. When you begin to get into the 8 to 10% and higher range it adds more luster to the color due to increased light reflection from the crust but that's about all that you get. Consider some of the pastry items where the total fat content is closer to the 20 to 25% range, or look at pie crust where the fat is around 30 to 35%. Most of the color there is due to the application of egg wash to the item prior to baking or the use of corn sugar in a pie crust or milk on it as a wash where the lactose in the milk is providing the color. In all of these though the color is more lustrous due to the high fat content but not darker.

When oil is used in the pan for making pan type pizzas you will consistently see a fried effect and a darker crust color where the dough was in contact with the hot fat and fried but again this is a topical thing ant based on the oil/fat being in the dough, think of a tortilla....on average 8% fat is used in that dough...think about the color, what color?

[Re: Does oil affect crust color?2114](#)

It works pretty well to soften the hard lumps of brown sugar.

[Re: Anyone tried this for storage?2115](#)

Additionally, if you're just changing from ADY to CY you would use twice as much CY as ADY.

[Re: Conversion from ADY to CY and Cold Fermenting2116](#)

The bread is about 40% total moisture content and the apple peel is almost 90% moisture so moisture migrates to the driest of the two (the bread), thus increasing the moisture content, this makes it more moist but doesn't impact staling at all.

[Re: Anyone tried this for storage?2117](#)

Edward05;

Good grief! Sugar and oil look to be all "outta whack", but can't be sure since all ingredients are shown in volumetric portions instead of weight measures. If you are going to be making dough for just one 12" pizza you will need to have about 10-ounces (285-grams) of dough for a thin crust or 14 to 16-ounces (398 to 454-grams) for a deep-dish type of crust so you will need to have a grams scale to weigh out your ingredients with doughs.

The first thing that needs to be done is to get some actual weight measurements on each of the ingredient portions which you have shown, once you have provided that we can then put the "recipe" into a dough "formula" and convert it, very accurately, into any dough size you want. But keep in mind that with such small dough sizes your ingredient amounts will be quite small and shown in grams weight so you will need to have a scale capable of at least weighing to the nearest gram for weighing the ingredients for making your dough.

[Re: Breaking down dough recipe for one pizza 2118](#)

Absolutely correct, couldn't have said it any better. If you put it ON the dough prior to baking it will impact the crust color more than putting it into the dough.

[Re: Does oil affect crust color?2119](#)

75-years young!

I've seen a lot of water pass under my bridge.

[Re: wet doughs2120](#)

I normally have a metal bench scraper in one hand too which I use to help lift the dough off of the bench, after a few stretch and folds the dough will begin to get

sufficiently developed so as not to require the use of the bench scraper to help lift it. I learned this technique back in the late 50's when working for a small retail bakery and making Danish dough. Not a very high absorption dough but as it contains up to 20% sugar it's super soft and sticky and all but impossible to handle any other way until you get a little gluten development and get the dough chilled.

Re: wet doughs 2121

Hillbillypizza;

Weighing in on your questions;

- 1) Don't cook it. If you do the sauce will lose flavor after being baked on the pizza. Additionally you will run the chance of scorching it which would destroy the flavor and once it is cooked you will then need to cool it back down to 40F or less for holding.
- 2) You might want to consider using sheet pans and single bags to cover each sheet pan of dough balls. This is a widely used method for cold storage of the dough balls. Make sure the bags are at least 8-inches longer than the pan which will allow the bottom of the bag to be folded up over the end row of dough balls and the top of the bag to be folded down over the end of the pan and tucked under the pan. In this application the pans are usually stored in a rack in the cooler. The bags can be reused a number of times, my suggestion is to use the bags for a full week and change out weekly.
- 3) Opening the dough balls using a rolling pin is fine for a thick crust, just be sure to open the dough to a diameter slightly larger than the pan itself as the dough will exhibit some memory as you place it into the pan. With this said, you will need to allow the formed dough to proof in the pan prior to baking. We normally like to proof for 45 to 75-minutes (you will need to experiment to see what time gives you the finished crust you're looking for). If you want a raised edge on the crust the time to form it is just prior to baking, do this by pulling some of the dough up onto the sides of the pan using your fingers (this will typically result in something of a Chicago pan style of raised edge). If you want to have a more rounded raised edge prepare the pan using a shortening (plastic fat) like the U.S. product Crisco. Using this in the pan will allow you to place the dough ball into the pan and press it out to fit the pan without the dough pulling away from the pan, this will allow you to form an edge at this time which will create a rounded edge on the finished/baked crust.
- 4) A par-baked crust does not need to be refrigerated, it can be stored at room temperature without any issues at all. Some find it easier to par-bake their crusts with 1/2 of the sauce applied to the skin prior to par-baking (helps to avoid bubbles), the remainder of the sauce is then applied when the crust is used to make a pizza. These par-baked crusts can also be stored at room temperature. I do not recommend carrying par-baked crusts over from one day to the next.
As to your question on slices, yes it will impact the overall quality of the presentation BUT if you refreshen the slice by adding a LITTLE fresh cheese to the slice at the time of reheating it can make a big difference in perceived quality. A quick spritz of EVOO onto the top of the slice as it goes into the oven can also make a big difference too.
- 5) Pre-cooked bacon bits, in my opinion, is the only way to go. As for toppings/mushrooms just make sure they are thinly sliced and don't overload the pizza with them and you'll be fine, we do it all the time.
- 6) Have you explored the Internet for ideas? Lots of them out there. One of my favorites is to use a commercially prepared Ranch Dressing to which I add dried dill weed or basil pesto. Or make your own Ranch Dressing and doctor it up. A plain old vinegar and oil with mustard also works well. This is a good opportunity to let your imagination run wild.

By the way, when I did pizzas in Korea I found that substituting small pieces of dried squid for the bacon bits was a very popular topping too. You might give some thought to a seafood pizza using Alrbedo sauce (no red sauce) then sprinkle with dried dill weed, add THIN SLICED seafood, garnish with fresh onion, and tomato slices. Top with a 1/2 application of a 50/50 shredded mozzarella and Parmesan cheese. Drizzle with EVOO as soon as it comes out of the oven.

[Re: Few questions before my shop opens 2122](#)

Yes, that certainly puts a different slant on it :-D

[Re: Few questions before my shop opens 2123](#)

Lots of things to cover there, please call me at 785-537-1037 as soon as possible and I'll be glad to answer your questions for you.

[Re: Few questions before my shop opens 2124](#)

62 to 66% depending upon how skilled you are at opening the dough balls into skins.

[Re: WFO \(Ooni Pro\) temp and time for NY Style? 2125](#)

I've found that some of my dough formulas end up sticking to the plastic bag if I don't lightly oil the dough ball, just like the dough balls always end up sticking to the bottom of the commercial dough boxes, hence the need for a scraper to remove them from the box. I really like the idea of the plastic containers...that's a pretty cool idea! Just make sure the dough doesn't expand too much.

[Re: Making pizza at home, thin crust NY style 2126](#)

So it's not really a whole-wheat dough it's just a "wheat-dough". By regulation, whole-wheat cannot contain any whiter flour. Unless the label reads "whole-wheat" the amount of white flour can be anything from 1 to 99% of the total flour weight. As the label shows whole-wheat flour first the amount of whole-wheat flour in this case should exceed the amount of white flour, but by how much?

[Re: Lamonica's Frozen Dough Ball 2127](#)

Agreed.

[Re: Does container size matter 2128](#)

Ditto.

All Trumps is the "go to" flour for New York style pizza, but in truth, any good bread flour will work well unless ya just gotta have all the chew possible, then go with All Trumps, for most though, they like to temper the "chew" factor down a bit and use lower protein content bread type flours to accomplish this.

[Re: Making pizza at home, thin crust NY style 2129](#)

With a poolish you are also adding acids in addition to fermenting yeasts and bacteria so, depending upon the pH of the poolish it could very well be acidifying the dough which would result in accelerated fermentation due to the acidified dough.

A poolish, can impart a different flavor from a regular yeast leavened dough just like a liquid ferment (brew) produces a different finished flavor than a yeast leavened straight dough process. As for like or dislike, it all depends upon where your taste preferences lie.

[Re: Low IDY = D.O.A. 2130](#)

With stout and bison who could ever resist it? :-D
And the pecans, well....that's just icing on the cake! :drool:
[Re: Faux sourdough?](#)**2131**

Amen to that! ^^^

Remember the discussions we recently had concerning insect fragment counts in flour.

An interesting point: Figs, the flower of the fig tree is pollinated only by mites (fig mites), they cannot be separated from the figs during processing so fig mite fragments are present in fig past at a high count. This is allowed so long as they are "fragments" meaning that they have been processed and not introduced post processing of the fig. I happen to have a fond liking for Fig Newtons and when our kids were small I used to tell my wife and kids this story embellished with: "Now you know why Fig Newtons are kinda crunchy inside". Those Fig Newtons were ALL MINE from that point on. OK, truth is it was the fig seeds (like sesame seeds) that make it crunchy), none of them will eat Fig Newtons to this day.

[Re: 25kg bag questions](#) **2132**

That is absolutely correct. A number of years ago most white breads were made with 4 to 5% sugar added to the dough formulation which wasn't too bad since a good portion of the sugar was metabolized by the yeast but today we find that the sugar levels are increasing with some white breads containing up to 8% added sugar (sugar and fat sell) and if you think that's bad, think again, the popular whole-wheat breads quite often contain 10% or more added sugar to off-set the bitterness of the bran which is present from the whole-grain, and if you look at some of the specialty (soft and sweet) breads the sugar level jumps to close to 20%. Kinda makes the worst pizza crust formulation look pretty tame. If one was to use little (not more than 2%) sugar or no sugar, and ferment the dough out to 2-days or more, use a sauce with no added sugar, go easy on the cheese and select the toppings carefully (vegetables, skinless chicken breast, fish, etc.) pizza, in moderation, really isn't all that bad. We did a study on a pizza made in this manner a good number of years ago and we found that a lightly cheezed (no other toppings) pizza had a similar caloric density to white bread, meaning that a 2-ounce slice of white bread provided about the same calorie contribution as a 2-ounce slice of the cheese pizza. When it comes to pizza, I used to say that it suffers from the potato chip syndrome: You can't eat just one (chip or 2" X 2" slice).

[Re: Natural sugars in flour. Breaking down the Carbohydrates. How healthy is it?](#)**2133**

As for baking results in a home baking environment you probably won't see too much difference BUT you might want to think about buying a cheap flour sifter as this will keep you informed of any unwanted infestation problem which potentially could crop up. Look for the little cigarette and confused flour beetles as well as Indian meal moth whose presence is identified by its web which results in what we see as clumping of the flour. Also look for any larvae that might be present. My advice to home bakers is to sift the flour after a month and turn the screenings (anything that didn't go through the sifting screen) onto a clean paper towel where you can inspect it for insect presence. If consuming a few bugs doesn't bother you disregard the above, they won't hurt you, just a little added protein in your diet.

[Re: 25kg bag questions](#) **2134**

Frenchy2000;

This same question has been addressed a number of times so you might want to

look through the archives here to get a bigger picture of what others do. My approach is to break the large bag down into smaller bags which I label and store in the freezer. When I'm ready to use the flour I remove a bag and allow it to warm back to ambient for at least 24-hours before opening the bag. Then you can use from the opened bag for a month or more. That which is stored in the freezer will remain good to use for a very long time, at least 10-years. I do not recommend storing flour for much more than a few weeks at room temperature unless you are fond of salt and pepper flour aka "buggy" flour. Additionally, once the flour has been frozen for a period of 30-days or more, not just in the freezer, but FROZEN, so consider 45-days in this case, it can be removed from the freezer and stored in an insect proof container for several months. This flour will not develop an insect infestation due to any intact insect eggs or larvae in the flour as the long term freezing will kill them but it is still prone to infestation from the outside, hence the insect proof containers. Now the only thing that will happen over the next few months will be natural oxidation of the flour. as close as we have been able to determine, this natural oxidation, over a 12-month period, is about the same as adding 15 to 20-ppm potassium bromate to the flour. This means that the flour will exhibit greater strength characteristics over time which may manifest itself by increased dough memory/snap-back and possibly greater oven spring characteristics. If you want to prevent the oxidation issue the only option you have is to keep the flour frozen until you're ready to use it.

[Re: 25kg bag questions](#) **2135**

With all things combined, cold dough temperature, low IDY and high salt I'm guessing that the yeast really wasn't able to do much so there would have been little to no biochemical gluten development. Maybe experiment with increased finished dough temps...shoot for 75F to see if that helps.

[Re: Low IDY = D.O.A.](#) **2136**

With exception to the low salt level it looks like a pretty good no-time dough formula.

[Re: The dough recipe on a Fleischmann's yeast packet](#) **2137**

The purpose for adding steam during the baking of crusty breads is to allow for greater oven spring during the first minutes of baking. We usually figure that the steam is most beneficial during the first 20% of the total baking time, after that the steam is vented from the oven and the bread is baked in a dry oven. In a way, pizzas are already baked with steam since the top of the pizza is cooled through evaporation of water from the sauce and toppings, this cools the air and this cooler air flows down around the pizza during baking (deck ovens and stone hearth ovens only). The addition of more steam might result in greater oven spring for an even larger raised edge, if that's what one is looking for but like I said, just for the first 20% of the baking cycle. Remember also that steam has a cooling effect upon the baking chamber so expect baking times to be a bit longer. Also, if the oven is not designed for steam application significant damage can result over time to the metal frame/superstructure of an oven if steam is used regularly. During baking the oven cavity is filled with acids released during baking (by products of fermentation/acetic, lactic and propionic acids), these acids are carried by the steam and when they contact something cooler condensation takes place, then the heat of the oven removes the water leaving behind concentrated acids which raise havoc on any carbon steel part of the oven, it's like a cancer, first you see the rust that wasn't there before then the rust does its work over time, and there is no acceptable way to really address the problem.

[Re: Steam in a pizza oven](#)**2138**

Why would you want to sand a metal peel? If you have a lot of "gunk" on it and you want it to look pretty just soak it in hot water (no soap) and go at it with a scrubbing pad. A wood peel can be sanded with very fine (600-grit) sand paper to remove any roughness and improve release properties but a metal peel is best relegated to removing the pizzas from the oven. In all of my 50+ years working with pizza I only found it necessary to sand my metal peels on the leading edge if they got beat up by slamming them into the back of the oven, I don't think I ever had to sand the entire peel, with that said, we did wash all of our oven peels at the end of each day so they stayed pretty clean.

[Re: Should I sand my metal peel?](#)**2139**

Actually, vinegar isn't added to cakes to react with the baking powder, it is added to react with baking soda (big difference). Baking powder is a fully balanced leavening system, just add water and heat and it generates carbon dioxide as a leavening gas. Baking soda, on the other hand, will only make the cake more alkaline (too much will turn the fat in the cake into soap through a process called "saponification" resulting in a soapy flavor in the finished cake. When vinegar (dilute acetic acid) is added along with the soda the two quickly react to form carbon dioxide as a leavening gas. The only reason for adding vinegar or any acid to a cake batter with a fully balanced leavening system is to adjust the finished pH of the cake, making it more acid which is common in white cake and angel food cake as it produces a brighter, whiter crumb color. Soda, on the other hand is commonly added to chocolate cake as it makes the crumb darker and intensifies the chocolate flavor (dutched process cocoa is just cocoa treated with an alkali to make it darker and more flavorful).

Now to pizza dough. The reason for adding vinegar to pizza dough or any yeast leavened dough, is to acidify the dough slightly, thus helping to "jump-start" the yeast with fermentation. Since acetic acid is one of the acids formed during fermentation it will also help to lower the pH of the finished crust but not much below pH 4.2 (sourdough has a pH of 3.8 or a little lower), so its impact upon the finished flavor is marginal at best if the dough is already being properly fermented, where there is some benefit is in doughs that are fermented for only short times, in this case the lower dough pH will help to speed up the rate of fermentation and give a lower finished crust pH for a slight flavor improvement over a short time fermented dough without added vinegar. How much vinegar is added? Typically 2% of a 50-grain strength vinegar is used, be sure to remove 2% water when adding 2% vinegar.

[Re: vinegar in the dough](#)**2140**

The dough absorption and the yeast levels are not fixed, they are to a great extent variable depending upon how the dough is being managed and to some extent the skill set for the pizza maker with lower absorption levels being easier for the beginner/novice to handle, then once mastered they can experiment with higher absorption levels. Point is, use whatever works best for you in your specific case. That said, 0.375% IDY and 62% absorption is usually a pretty good starting point unless there are mitigating circumstances such as an unusually high or low absorption flour or a very high oil level in the dough formulation, or a fridge that doesn't hold temperature very well, or failure to follow good dough management practices which usually dictates a very low yeast level.

[Re: Dough Recommendations - Two Scenarios](#)**2141**

And don't forget to get them involved in the pizza making process, there's nothing better than knowing that you made the pizza and now you're about to enjoy eating it, and your kids will love you for the fact that you got them involved with making pizza and hopefully carry on the tradition. :)

[Re: yung dad looking for pizza connections](#) **2142**

I think you're wasting your time by pre-heating a pizza tray/pan as the metal won't hold enough heat to make much of a difference. Next time try just putting the skin directly onto your lightly oiled tray, then dressing it and placing it in your oven about 1/3 of the way up from the bottom, after about 7-minutes move it to a high position being sure to spin it 180 degrees as you place it onto the higher rack position.

To address the light crust condition you might need to include some sugar in the dough formula, 2% would be a good place to start at. My home oven also has a top broiler coil so I turn it on when I get ready to move the pizza to the higher rack position.

[Re: Some newbie questions](#) **2143**

Sauce is roughly 90% water, as the water evaporates from the sauce it cools the top of the pizza keeping it from baking/setting as fast as the remainder of the pizza this is what prevents the bubbling of the pizza and it also helps to form a thinner top crust. We try to make it a practice to put half of the sauce on a skin before we par-bake it for this very reason.

[Re: Problem making cheese first pizza](#) **2144**

The sugar helps to keep the moisture in place and the fat helps to slow its rate of migration. This is one reason why you don't see cakes shrinking like breads and rolls.....high levels of fat and sugar.....two important food groups. :-D

[Re: Crust gets dense after frig leftover](#) **2145**

The dough that you are using might be a commercially frozen dough which means that it has not received any fermentation what so ever. Try slackening the dough out in a lightly oiled bowl in the fridge for 12-hours, then bring out to room temperature for 1-hour and place back into the fridge for 24 to 48-hours. We developed this procedure for pizzerias using frozen dough balls and it works quite well.

Note: Dough that is insufficiently fermented has a propensity to bubble.

[Re: Problem making cheese first pizza](#) **2146**

The biggest problem with pans in deck or stone ovens is that of the bottom getting too dark before the rest of the pizza is finished baking. This is easily addressed by placing a pizza screen under the pan.

[Re: Pizza Pans](#) **2147**

As the crumb structure cools it shrinks (becomes tighter) and then as moisture migrates out of the more moist crumb section to the less moist crust portion it shrinks even more. You even see this with bread where you see the entire loaf shrinking. The shrinkage is so pronounced that when measuring the volume of a loaf of bread using the rape seed volume displacement method you have to measure the volume of all loaves being measured at precisely the same time, otherwise waiting an extra 5-minutes will produce a smaller loaf due to the shrinkage.

[Re: Crust gets dense after frig leftover](#) **2148**

To me that looks like a lot of sauce.

[Re: Help keeping my toppings on](#)**2149**

When putting the cheese right on top of the dough I never use shredded, instead I like to use sliced. Being from Chicago that's an old habit that's hard to break away from.

[Re: Problem making cheese first pizza](#)**2150**

It's kinda hard to use the term "par-bake" incorrectly. Like you, I've heard these types of claims before but they were made many years ago back before most people really understood what hot pressing was all about. I launched a huge campaign to educate people on hot pressing of pizza crusts more than 30-years ago and to dispel the false belief that hot pressing actually par-baked the dough/crust at the same time as forming. I guess I missed a few people. Your beliefs are spot-on and if you ever find any validation to a hot pressed crust being par-baked as it is being formed please let me know. During the hot press forming of the dough into a skin only the outer surface area of the dough gets hot, not the center section (which is still raw). In order for a dough/crust to be par-baked it must reach a minimum internal temperature of 180F but most will target 185 or even 190F to ensure the crust is thoroughly baked (par-baked means that the product is fully baked BUT without the development of crust color or minimal crust color).

Your instincts are good! :)

[Re: Anyone actually par bake with a dough presser?](#)**2151**

That is correct, you can indeed adjust the crust color of your pizzas by adjusting the amount of sugar used in the dough formulation, sometimes when we have an uncooperative oven we can improve upon the bake a bit by adjusting the sugar level up or down a little. An infrared thermometer is an excellent idea for measuring the deck temperature and setting your oven up don't worry about what the thermostat or whatever says, go by the readout from the IR thermometer.

[Re: Crunchy Dough](#)**2152**

The DoughXPress like the DoughPro press and all other hot presses, DOES NOT create a par-baked crust in any way, shape or form. Anyone who tries to tell you that it does doesn't know what they're talking about. The hot press heats the dough to both relax it for ease of forming under the press head and to help it retain its shape after press forming. If the heat is applied to both sides of the skin during forming like it is with the Little Toro hot press from AM-Manufacturing the heat creates a dry skin on the surface of the crust which allows it to be placed directly onto a belt/conveyor for further proofing prior to further processing such as dressing and or baking or even freezing.

[Re: Anyone actually par bake with a dough presser?](#)**2153**

Is there not a heating element on the bottom of the oven too? If your oven only has a top element you might not have a "pizza" oven but instead a "baker's" oven which is significantly different. Also, 4 to 5-minutes baking time in a deck oven is pretty short as most deck oven bake a pizza in the 6 to 7-minute range for a single pizza and then when loaded the time jumps to around the 9 to 11-minute mark.

[Re: Crunchy Dough](#)**2154**

Since you have a preference for the flavor imparted by CF (as I do also) why not just go straight to balling after mixing and dispense with the RT part? This will

allow you to control the fermentation a bit better through manipulation of the finished dough temperature but more importantly it will allow the dough balls to cool down more efficiently allowing the refrigerated temperature to effectively slow the rate of fermentation. With the RT phase first you are balling a gassy dough which is a much better insulator than the dough right after mixing, combined with the heat of metabolism your dough most likely isn't cooling off sufficiently to provide you with the CF time you are targeting before becoming over fermented.

[Re: When the right fermentation turns wrong](#)**2155**

Pretty much so. It's an old method of leavening the dough but it does have its limitations since yeast doesn't multiply/divide under normal dough conditions you are adding less and less yeast every time you do it so fermentation times need to be progressively longer with each use. This is different from a true starter which is based on bacteria (lactobacillus/lactic acid forming bacteria) propagation in addition to yeast cells which are present in the air.

[Re: Yesterday's dough as starter](#)**2156**

I'm assuming you mean crust and not dough as crunchy dough is waaayy different from a crunchy crust. You have my curiosity up when you mention differences in stone and oven temperature...this is not common for a commercial oven. As for the handling properties of the dough when you open it, are you allowing the cold dough balls to warm to 50 to 60F (50F is the most commonly used temperature for use in a pizzeria) before you begin opening them into skins?

[Re: Crunchy Dough](#)**2157**

If you are converting from CY to ADY you use only half as much ADY as CY. But don't forget to hydrate/activate the ADY in 100F water before adding it to your dough.

[Re: Yeast Amounts & Fermentation Times - please help](#)**2158**

If your crust isn't browning sufficiently with the reduced bake time try adding some or more sugar to the dough formulation to promote crust browning.

Ever have a Papa Murphy's pizza? 5% sugar. Can't say I like their sweet tasting crust but that's how they get their crusts to brown consistently in home ovens. If I was on their development team I would have used whey instead of sugar to promote crust color development, whey is roughly 70% lactose (milk sugar), it's a reducing sugar so it browns quite nicely, it is non-fermentable by baker's yeast so the amount doesn't change with the age of the dough and best of all, it's the least sweet of all the sugars so it doesn't impart sweetness to the finished crust flavor profile. Typical use levels are 8 to 12%.

[Re: Pizza toppings](#)**2159**

The most common cause of this is due to using too much sauce. Try making a pizza with minimal sauce, if that works out better you know what the issue is, then you can begin to increase the amount of sauce until you find a happy compromise.

[Re: Help keeping my toppings on](#)**2160**

If you're scaling up from 12-inch to 16-inch the surface area of a 12-inch circle is 113-square inches and the surface area of a 16-inch circle is 201-square inches (those numbers are rounded off). The difference being 88-square inches so if we divide 88 by 113 = 77.876 (78) we see that a 16-inch pizza is 78% larger than a 12-inch pizza so all things equal a good place to start is to scale your dough ball weights 78% heavier than you do for the 12-inch format. Ditto for cheese and

sauce. While not 100% accurate this will get you very close to where you want to be.

[Re: Please recommend how much AT flour for 16" thin crust, small rim, NY pizza](#)**2161**

When IDY made its first appearance here in the U.S. back in the 60's people would return the packages thinking that they were bad because they were so hard. Actually, it's the soft packages that are bad as the vacuum seal has been compromised on those packages.

By the way, there is no such thing as a silly or ridiculous question, but there is such a thing as someone who is too silly to ask a question.

[Re: Saf-Instant Yeast](#)**2162**

Actually, there is no such thing as "instant compressed yeast". There is instant dry yeast (IDY) and compressed yeast which goes by a bunch of other names too (see my post in the question on C.Y.). To reconfirm, yes, SAF, IDY is the same as "IDY" the SAF part just references the manufacturer of the IDY.

[Re: Saf-Instant Yeast](#)**2163**

C.Y. = compressed yeast/cake yeast/fresh yeast/brick yeast/block yeast/baker's yeast/wet yeast and more recently crumbled yeast which is the same as all of the other except it is sold in crumbled form (only in 50# bags). C.Y. is the same as all of the above, they are just referenced by different names.

[Re: What does CY stand for?](#)**2164**

Maybe too much cheese?

[Re: Pizza toppings](#)**2165**

Yes it does, for every ounce of flour that is incorporated into the dough it's like reducing the amount of water in the dough by about 1/2-ounce BUT most of the flour you see being brandished about really isn't incorporated into the dough so the impact really isn't all that great.

[Re: Flour after initial mix and effect on hydration %](#)**2166**

Philia36;

Ira is spot-on. Look for a temperature of around 800F or a bit more for a true N.Y. presentation.

[Re: WFO \(Ooni Pro\) temp and time for NY Style?](#)**2167**

Change the bench kneading time to something closer to 20-minutes and the answer is yes. A planetary mixer can mix a dough as well as a spiral mixer in many cases (if the planetary mixer isn't too old and tired) but if can only do so with a specific amount of dough in the bowl too much or too little dough and it doesn't get mixed as well as it should as the dough either grabs onto the hook and receives little mixing action or it either climbs up the hook or gets forced to the top of the bowl where the dough doesn't get the contact needed with the hook for proper mixing action. The spiral mixers handle doughs of different sizes quite well with very consistent mixing results across all reasonable dough sizes.

[Re: Ok Tom... what gives??](#)**2168**

Your question on the different forms of yeast;

The amount of water that you suspended the yeast in will have an impact upon what you see on the surface. A good amount of water would be about 5X the weight

of yeast , with more water you should still see a few bubbles but not a "foam" forming over the surface of the water.

IDY should be suspended/activated in 95F water while ADY 100 to 105F is better. For suspending CY 100F water is recommended. If you are experiencing an initial slow yeast fermentation rate it is probably not due to the mineral content of the water unless you have sulfur water but instead the pH (acidity) of the water can/will have a dramatic impact upon how the yeast ferments initially. High pH (above 7.5) water can slow yeast activity until acids are formed through fermentation at which point the fermentation rate will gradually increase. Slightly acid water (below pH 7.0) is good for the yeast as yeast performs well in a moderately acid environment. It's easy to measure the pH of your water using litmus strips available from a pharmacy or pool supply outlet.

On a personal note: We are also on our own private well (120-feet deep) with great water but we also have a lot of limestone here and that is reflected in our water pH of 7.8. In other wells I've seen it as high as 8.2. Not a big deal, I just replace 2% of my dough water with white vinegar and everything is good. If this were a pizzeria I'd opt to use 0.25% (based on flour weight) MCP (mono calcium phosphate) instead.

We have discussed this in posts about water previously and I wrote an article on the topic some time back.

[Re: Some Unanswered Questions](#) **2169**

I wish I had an answer to that question, but I don't. There are many more different designs of home dough mixers than there are commercial mixers and as you have heard me say many times before about ovens, "Every oven is a law unto itself and only itself", the same might be said for home mixers too. When it comes to commercial size mixers it seems that the manufacturers are more interested in duplicating a design as opposed to improving upon a design, where as with home mixers there seems to be more emphasis on improving a design. With the increase in home baking over the past few years there seems to be a trend towards better (more powerful and better mixing action) home mixers and I'm really glad to see an increase in interest in spiral design mixers for home use.

[Re: Ok Tom... what gives??](#) **2170**

While there is no standard of identity or specification for "hi gluten flour" most would generally consider any white flour in the 12 to 14% range as "hi gluten"

[Re: High Gluten Flour](#) **2171**

I always enjoy hearing how others make their pizzas. :chef:

[Re: Why is my dough floppy](#) **2172**

Actually, you're posing two different questions, the difference between the performance characteristics of a hard wheat flour and a soft wheat flour as well as the difference in performance due to protein content.

Hard wheat flour v/s soft wheat flour: A lot of the performance characteristics will depend upon the varieties of wheat making up the grist that is being milled but in general, the gluten structure obtained with a hard wheat flour will be stronger than that from a soft wheat flour, think softer, more extensible doughs with soft wheat flour. Additionally, soft wheat flour typically do not have the fermentation tolerance exhibited by hard wheat flours as they tend to show more of the effects of fermentation, especially when longer fermentation times are employed. Some of the "00" flours reflect this difference by stating that specific "00" flour types are designed for long or short fermentation doughs, and they are correct, if you give a

short fermentation designated flour a long fermentation time the dough can get pretty soft and extensible, probably more than what many people would care to work with.

As to the difference in protein content, in this case you have to compare the protein content only from hard wheat varieties, work that I did back in the 80's clearly showed that doughs were equally as strong when made using flours of the same protein content whether the flour was milled from a hard red spring wheat grist or a hard red winter wheat grist. We found this to be true over a wide range of protein levels. In our view at the time these results totally debunked the premiums paid on spring wheat over winter wheat at the time, kinda irritated the branch of the U.S. Government responsible for the export of U.S. wheat at the time.

[Re: Soft wheat vs. Hard wheat](#)**2173**

Have you looked at Provolone cheese? Similar to mozzarella but with a higher fat content. When we did our pizza seminars one of the cheese blends that we used was a mozzarella - provolone blend (75/25).

[Re: Help finding good cheese retail](#)**2174**

Oregon has at least three major pizza or pizza crust manufacturers that I can think of. That says quite a bit about both Oregon and pizza considering where/how the state is located in regards to major metropolitan areas. We only have one here in Kansas, Schwan's Foods but their distribution is a full 360 degrees. They even truck their pizzas all the way to Pennsylvania and back-haul with a load of pepperoni.

[Re: The most popular frozen food in every state](#)**2175**

QJ:

Based on all of the things that you've mentioned, it appears that indeed there might be a common denominator. Finished dough temperature (now lower with your new spiral mixer) would prove to be a reasonable explanation. As for the difference in mixing action between a planetary mixer and a spiral mixer, the planetary mixer with a dough hook develops the gluten by driving the hook into the dough and pulling it slightly from the side of the bowl while the spiral mixer develops the gluten using a true stretching and pulling action, sound familiar?

That's the same action exerted on a dough when it is kneaded. This action exposes a greater dough surface to the air for better oxidation of the gluten forming bonds resulting in a stronger and drier feeling dough, it also works to help align the gluten for a smoother dough feel (this is just like giving the dough a little kneading after it has been machine mixed). At the same time a spiral mixer tends to mix the entire dough, regardless of size, all the same while a planetary mixer tends to mix different size doughs somewhat differently, especially where large size doughs are employed. The one exception to this appears to be the new HL-Series of Hobart planetary mixers, with these mixers we still see a difference with smaller size doughs but when you get into the larger size doughs for the bowl capacity there doesn't seem to be as much, if any difference between say a half size dough and a full capacity sized dough.

I'm glad to hear that you and your crew are seeing the benefits of your new spiral mixer, now if they could just figure out a way to make sauce in them? :)

[Re: Ok Tom... what gives??](#)**2176**

I think a lot has to do with preference. To me, adding EVOO to the dough is a waste of a great product since many of the aromatics are lost during the baking process but by putting the oil on post bake (immediately after removing the pizza from the

oven) allows the heat of the pizza to "pop" / release the aromatics from the EVOO giving the pizza a wonderful aroma as well as taste.

[Re: Olive Oil Pre-Bake or Post-Bake](#) 2177

Sure, here's a formula and procedure to work with.

Flour: 100% 500-grams.

Salt: 2% 10-grams.

Sugar: 2% (optional) 10-grams.

Oil: 2% 10-grams.

IDY: (instant dry yeast) 0.375% 1.875-grams

Water: (65F) 62% (variable) 310-grams.

Put water in mixing bowl.

Add salt and sugar (if used) no need to stir.

Add the flour, then add the IDY right on top of the flour.

Mix at low speed just until all of the ingredients are incorporated and no dry flour is seen in the bowl.

Add the oil.

Mix at low speed for 1-minutes.

Mix at the highest speed possible without stressing your mixer for 8 to 10-minutes or just until the dough is smooth. Check the finished dough temperature, you are looking for a targeted temperature of 75 to 80F.

Remove dough from mixer and place on floured surface, divide into 300-gram dough pieces.

Round each piece into a ball and lightly oil.

Place each ball into individual plastic bags (food bags or bread bags) NOT Zip-Lock Bags.

Twist the open end into a pony tail and tuck under the dough ball as you place it in the fridge.

Cold ferment the dough for at least 24-hours (48-is better) and you can go as long as 72 to 96-hours.

To use, remove dough from fridge, allow to temper AT room temperature for about 2-hours or until the dough ball reaches 50 to 60F.

Roll bag down around the dough ball and invert over a floured surface, flour the dough piece and open into a skin to 12-inches for immediate dressing and baking.

Bake preferably on a stone or steel at 550F or hotter. If you don't have either, a seasoned screen will do in a pinch until you can get one.

Note: Any unused dough balls can be placed in the freezer not more than 48-hours after the dough is made. The frozen dough will keep for about 10-days in the freezer. To use the frozen dough transfer the frozen dough ball from the bag to a suitably sized bowl that has been lightly oiled, cover with a lid or stretch wrap, place in the fridge for 24-hours to slack-out (thaw), turn out of the bowl directly from the fridge onto a floured surface and partially open the skin to about 8-inches, cover and allow to rest for 20-minutes, then finish opening to 12-inches for immediate use.

[Re: Making pizza at home, thin crust NY style](#) 2178

It's actually not the significance of hard v/s soft wheat it's just the fact that the "00" flour is not malted or treated with amylase enzymes.

[Re: Soft wheat vs. Hard wheat](#) 2179

The problem you're experiencing is due to insufficient gluten development. In your case I think it might be due to less than ideal biochemical gluten development

caused by improper use of ADY complicated by a cooler than what might be desired finished dough temperature.

Doing the easy things first, try suspending the ADY in a SMALL portion of warm (100F/use a thermometer) and letting it stand for 10-minutes to activate, then add it to the cool (measure the temperature) water. I would start with 70 to 75F water temperature and target as finished dough temperature (after kneading) of 80 to 85F. Then proceed as you normally do.

Suggestion: After the dough has been in the fridge for 2 to 3-hours divide it to make your dough balls, lightly oil each dough ball and place back into the fridge for the remainder of the CF period. When ready to use remove from fridge, allow to warm AT room temperature until the dough reaches 50 to 60F, then turn the dough ball out of its container onto a flour dusted surface and open into a skin for immediate use.

Let us know how this works for you.

[Re: Dough balls have rips in them??2180](#)

Any type of a dial AKA stem type thermometer will work. If it's electronic that's fine, if it isn't, try to get one with a hex nut under the head. This is the calibration nut, by holding the head firmly and turning the nut you can easily calibrate the thermometer. Best way to calibrate is to use an oral thermometer (designed to be most accurate at 98.6F) in a cup of water at a temperature that will read on the oral thermometer, place the stem of your thermometer next to the oral thermometer and allow time for the needle to stop moving, compare the temperatures and calibrate the stem thermometer if necessary.

[Re: Some Unanswered Questions2181](#)

The thing to remember about water is that it's the temperature of the water that is used to adjust the finished dough temperature. For many of us we are looking for a finished dough temperature someplace in the 70 to 85F range, for me I like to target 70 to 75F. A simple method for determining the water temperature is to use 145 minus the flour temperature with the difference being the water temperature.

[Re: Some Unanswered Questions2182](#)

Dpp83:

I think the first place for you to start is getting a scale that will weigh in grams. There are a lot of them available on the Internet priced very reasonably at around \$20.00. This will allow you to actually weigh each of your ingredients for much improved accuracy and consistency. If I'm reading your post correctly it appears that you are adding 100 ml. olive oil to 500-grams of flour weight which is 20% olive oil (much more than what is typically used in making thin crust pizzas, 0 to 4% might be considered to be a more "normal" range for oil in a thin crust pizza dough formula). The dough formula is only a part of the crispy crust equation, the other part is how you manage the dough and then how the pizza is baked.

To get you started, here is a well proven dough formula and procedure. Once you have master this one you can begin to make calculated changes or try other formulas and/or dough management procedures.

Flour (Pillsbury Bread Flour) 100%: 500-grams.

Salt: 2%: 10-grams.

Sugar: 2%: 10-grams.

IDY (instant dry yeast) 0.4%: 2-grams.

Water: 62% (65F): 310-grams.

Olive oil: 2%: 10-grams.

You don't say how you mix your dough so for now I'll ASSUME you are using a mechanical mixer.

Put the water in the bowl first, then add the salt and sugar followed by the flour and the IDY.

Mix at low speed just until the dough begins to come together then add the oil.

Mix again at low speed to incorporate the oil then mix at a higher speed to develop the dough, this should take 5 to 8-minutes. The time is not critical for now.

Check the finished dough temperature, ideally it should be 75 to 80F.

Take the dough directly to your counter top, remove it from the bowl, lightly flour it and begin scaling 300-gram pieces, this will make 12-inch diameter pizzas.

Form each piece into a ball and lightly oil each ball.

Place each ball into individual plastic bags (like bread bags) NOT ZIP-LOCK BAGS.

You can buy very economical food storage bags from the supermarket that will work very well for this.

To close the bag, pull the bag close to the dough ball, twist the open end of the bag into a pony tail and tuck the pony tail under the dough ball as you place it intro the fridge.

Allow the dough balls to remain in the fridge for at least 24-hours before using. They can go as long as 72-hours. The dough will probably be at its prime after 48-hours.

To use the dough remove from the fridge and allow to set AT room temperature until the dough ball reaches 50 to 60F internal temperature. Depending upon room temperature this will take about 2-hours +/-.

Turn the dough out of the bag by rolling the bag down around the dough ball, and inverting the bag over a floured surface allowing the dough ball to invert the bag as it falls from the bag.

Flour the dough ball and open into a pizza skin for immediate use.

Bake your pizzas on a stone or steel or a screen in a hot 450 to 550F oven. In a rack position about 2/3 of the way up (you will most likely need to experiment to see where the pizzas bake best in your specific oven).

This is really easy to do and once you get the hang of it you will enjoy experimenting with different dough formulas, dough management procedures as well as pizza styles.

[Re: Why is my dough floppy](#) **2183**

Here is what I've done in the past when an error such as this was made at a pizzeria.

Make another dough but do NOT put any salt in the dough. Mix the dough just until

comes together and forms a nice cohesive ball in the mixer. Remove the dough from the mixer and divide it in half. Now divide the dough with with 5% salt in half. Combine a half from each dough and mix until a smooth surface is achieved. Do this for the other two halves too. You will now have two doughs with, in your case, 2.5% salt in each. Freeze the surplus dough balls for use next week.

[Re: Too much salt in dough](#)**2184**

The interaction between the byproducts of fermentation and the gluten forming proteins in the flour is what's responsible for the rheological properties of the dough (the way it stretches and handles in general), not fermentation in itself. This is why a short time dough can have a lot of fermentation but still exhibit a lot of dough memory. The dough that came from the pizzeria was, in all probability, cold fermented for 2-days or more which, if managed properly, would give the dough pretty decent handling properties. It's not so much the dough formulation that makes the difference, it's how they are put together and managed that makes the biggest difference. Like I used to tell my students, brick castles and brick privies are all made using the exact same ingredients, it's how you put them together that determines the finished product.

[Re: Ok, what's different](#)**2185**

Whoa! Correction!

I see you are using 50% of 2% liquid milk. At that level you will see some improvement in the gluten film (drier and stronger) as well as a stronger crust color.

Sorry about that!

[Re: Milk in dough](#)**2186**

Jackitup is spot on, the good news is that the calcium in the milk helps to strengthen the gluten forming proteins in the flour and the lactose (milk sugar) content helps with the browning of the crust, like I said, that's the good news, the bad news is the amount of milk you're adding (liquid milk I assume) really doesn't contribute to either of these effects as the amount is much too low. To get any realized effect you need to have the liquid milk at about 40% of the total liquid (40% liquid milk + 60% water = 100% of the total liquid added). Or if you use dry milk solids you can use 5% but remember to increase the dough absorption by 1% for each 1% milk solids added. Also keep in mind that lactose sugar is not metabolized by bakers yeast so it is not a source of food for the yeast to feed upon. Additionally, if using liquid milk it is a good idea to scald the milk before using it as this will help to improve its baking properties. Due to the cost of milk we really don't see much milk being used anymore, instead we use soy flour to replace the protein content of the milk and calcium sulfate to provide the calcium and whey to provide the lactose (whey solids are about 33% lactose, and because lactose is the least sweet of all the sugars there is essentially no sweetness associated with whey or lactose).

[Re: Milk in dough](#)**2187**

There is a very decided advantage to applying a very light application of oil as a moisture barrier between the sauce and the crust when using par-baked crusts. Your sauce, and vegetable toppings are all roughly 90% water and are just looking for an excuse to water out during the baking process. The sauce though is the worst contributor to moisture migration into the crust, if you want to see how bad it can be just place a portion of sauce on a china plate and let it stand for 15-minutes, if you see a water ring around the sauce that's the water that would

potentially soak into the par-baked crust. The same can happen with raw dough but since raw dough has a higher moisture content than a par-baked crust the affinity isn't as great with the raw dough, but it can still happen. This is why it is usually recommended that the dough skin or par-baked crust be lightly brushed with oil prior to sauce application. Admittedly, the problem may not be as prevalent when making pizzas at home as it is when making pizzas in a commercial setting/pizzeria, this is because there is a greater potential for the pizzas to be pre-prepped at the pizzeria (which allows time for the moisture migration to take place) but even with home pizza making a lot of times we are pressed for time when making several pizzas so the pizzas might be pre-prepped thus setting the stage for moisture migration and the development of a "dreaded gum line" which also manifests itself as a limp pizza or a tough, chewy pizza, in any case, I've not seen anything good come to a pizza which has a gum line.

[Re: EVO Before Pizza Sauce](#)**2188**

Kinda salty I would think, not to mention its impact upon fermentation.

[Re: Need help!!!! Bakers percentage](#)**2189**

When we use the commercial dough boxes the dough balls are usually placed about 4-inches apart, in some cases maybe a little less depending upon the dough formulation and projected holding time.

[Re: White crust](#)**2190**

Properly cold fermented dough balls will slowly become gassy and continue to grow in size maintaining something of a round shape but more flat than the ball it was when it went into the fridge. I can't speak for cold fermenting dough as to what it should look like because we typically don't use dough boxes lie we do in commercial/pizzeria practice. In commercial practice the dough balls should not more than Just "kiss" or at the very most come together about 1-inch by the last day of use. If they do more than that the dough either needs to be cross-stacked longer or the targeted finished dough temperature needs to be lowered. Cold fermented dough in the fridge will not feel soft and supple as warm fermented dough will because the temperature causes the dough to become firm, this is why it's easier to open the dough ball into a skin if you allow it to warm to 50 - 55F before opening.

If you go to my web site <www.doughdoctor.com> and click on the option to learn how to make dough one of the first photographs you will see is a properly cold fermented dough ball being removed from the dough box, it actually gives you a pretty good idea of what a properly cold fermented dough should look like even for the home pizza maker.

[Re: White crust](#)**2191**

Fermentation flavor is a very complex thing, it is the result of the byproducts of fermentation at work on flour proteins as well as their residuals (mostly different acids/acetic, lactic and propionic) and a little alcohol too, but like the carbon dioxide most of it is long gone due to the baking process. Some people call it a "yeasty" flavor but this is incorrect as yeast actually has a musty taste (like old wet news papers), the taste/flavor they are actually referring to is the taste and flavor resulting from fermentation. Since acids are the main residual byproduct of fermentation this is why as fermentation progresses the flavor of the baked product may become slightly more acidic which has a good/bad influence on flavor. Like I said, it's a very complex thing, most people like it in moderation, some don't like it at all, and some can't get enough of it we used to call those people "sourdoughs" in

reference to their affinity to well fermented and/or sourdough products which are characterized by their pronounced acidic taste. By the way, there is a difference in taste, aroma and flavor. Taste is based just on the taste buds (coffee for example has a pronounced bitter taste), aroma is sensed only by smell and flavor is the combination of aroma and taste....look what happens to coffee when you combine aroma and taste, you get what we all relate to as "coffee".

[**Re: Refrigerate first or later?2192**](#)

So your dough is coming off of the mixer at 82F/28C.

If you were to ferment the dough for 24-hours at room temperature 77F/25C and then ball it for 24-hours fermentation in the fridge 2 - 3C/35.6 - 37.4F There would be little benefit from the cold fermentation as the dough would be so gassy as to insulate the core from much of a temperature change during the cold fermentation period. In my opinion, it sounds exotic but in reality it's an exercise in futility. In addition, with the RT fermentation coming first any change in finished dough temperature will create a significant change in the amount of fermentation the dough receives during that first 24-hours. Over the long haul you will experience quite a bit of variability in fermentation which can result in unexplained differences in the finished crust or the way it (the dough) handles.

Putting the dough in the fridge first for 24-hours CF and then giving it an additional 24-hours RT fermentation would provide greater overall consistency in the amount of fermentation the dough receives and since the dough wants to increase in temperature (dough increases in temperature due to heat of metabolism as the yeast ferments at the rate of about 1F per hour) it will take about 4 to 5-hours for the dough to fully warm to room temperature, depending upon dough size and the container, so you could figure on the dough ACTUALLY receiving close to 30-hours of CF with the remainder being RT fermentation. With the potential for inconsistencies in fermentation by the first procedure (RF followed by CF) and more overall fermentation I would think that the first process would give you a dough with potentially more extensibility and a finished crust with more of a fermentation flavor, ALL THINGS EQUAL, than dough made by the second procedure (CF then RF) which would exhibit much better overall dough consistency though less fermentation flavor due to the initial inhibition of fermentation by placing it in the fridge right after mixing and allowing it to slowly warm back to room temperature for the remainder of the fermentation period. While it is true that a different flavor profile is achieved under cold fermentation conditions than at room temperature fermentation I find it highly unlikely that one would find the difference significant in application (fully dressed and baked pizza) under the conditions you have prescribed.

[**Re: Refrigerate first or later?2193**](#)

Josh;

In this vein the test where you pull one dough ball for baking after 24-hours and the other one after 48-hours would provide some direction.

[**Re: White crust2194**](#)

Also need to know what the finished dough temperature is.

[**Re: Refrigerate first or later?2195**](#)

You will use about 60% absorption for the white flour portion and whatever absorption that is indicated for the barley flour, that will be your total dough absorption.

The test that you need to do will be done only on the barley flour as we need to

know what its absorption is before we can make a dough using it, especially at 50% of the total flour.

[Re: Need help!!!! Bakers percentage2196](#)

This is happening because you are not accounting for the high absorption of the barley flour. If you will go back through previous discussions on whole wheat flour you will find where I've written about how to determine the absorption of non-wheat as well as whole-wheat flours which absorb water so slow the dough looks normal at first but with time the "other" flour hydrates thus exhibiting a severe drying effect upon the dough making it hard/firm and difficult to work with and if you were to make a pizza from it disappointment would reign supreme.

[Re: Need help!!!! Bakers percentage2197](#)

I always use pitted olives and slice. As for onions I mostly use raw onions.

[Re: Good Results with Biga - Question about Olive toppings2198](#)

Yes it is, after stretching and fitting the dough for the last time you will need to experiment with how long to proof the pizza to get the desired finished crust characteristics. Some will go as long as 90-minutes while others as short as 30-minutes. In this case you will need to proof in 20-minute increments and take to the cooler (uncovered) for 45-minutes, then wrap or bag for storage. On the following day pull all of the pizzas for baking. Be sure to allow them to warm to 55-60F before dressing. So...you will be baking pizzas that were proofed for 20, 40, 60, and 80-minutes prior to being placed in the cooler. After baking pick the one that you like best and note the length of time it was proofed prior to being placed in the cooler. Problem solved. :)

[Re: Sheet pizzas2199](#)

Stretching dough from a ball to fit a sheet pan can be really troublesome, instead, ask the bakery to make the dough into 24-inch long loaves when they provide them to you. For a thin crust start out with 45-ounces of dough, for a thick crust try using 60-ounces of dough weight. You will find it easier to fit the dough to the sheet pan if you use shortening, like Crisco as opposed to oil.

Place dough onto greased pan (down the middle), cover and allow dough to warm for about 2-hours then use a pastry pin or rolling pin to roughly fit the dough to the pan, cover and allow to rest for an hour, using your hands begin fitting the dough to the pan (into the corners and up the sides) cover and set aside again for 30 to 45-minutes, give the dough one final fitting to the pan and it should be ready to dress and bake.

[Re: Sheet pizzas2200](#)

I've used it successfully to replace up to 25% of the regular white flour used in the dough formulation. Watch your dough formulation too as you will need to increase it a bit when using spelt flour.

[Re: Spelt2201](#)

Over fermentation can turn an otherwise great dough into slime or anything in between depending upon how much the dough is over fermented. This is why the dough handles so well after a fermentation period (it exhibits less memory characteristics/snap back). For home pizza making 75F is a good finished dough temperature to always shoot for however with so many different methods of dough management used in home pizza making this might easily be higher or lower for any specific application, but in general, 75F is a good number. For use in a

commercial application/pizzeria we commonly see finished dough temperature of 80 to 85F with an occasional 70 or 75F tossed in for good measure. Those lower temps are usually used where we have high shop temperatures or where long cold fermentation times (4 to 7-days) are being targeted.

[**Re: Dough Doctor New York Pizza Recipe Issue2202**](#)

Q.J.

Has it "nailed" spot on! ^^^

If you cover the dough right away it will sweat which results in an overly soft and usually sticky dough. The dough is also very slow to cool which further compounds the issue by leading to more fermentation than planned for within any specific period of time. In some cases the dough will actually continue to heat up in a covered container while in the fridge due to heat of metabolism (the heat generated by the yeast as a result of metabolizing nutrient during the fermentation process).

[**Re: Dough Doctor New York Pizza Recipe Issue2203**](#)

That's a lot like the dessert pizza that I've written about here a number of time. The difference is that I use a regular dough skin, brush it with melted butter and sprinkle with cinnamon-sugar mixture, then apply a cheese base made with ricotta, sour cream, and cream cheese which is blended with whole egg, sugar and salt, the viscosity is adjusted to that of mayonnaise so it can easily be spread on the skin about 3/16-inch thick, apple slices, peach slices, kiwi, sliced grapes, strawberries, blue berries, black berries, mango, banana or just about any kind of fruit you might have on hand can be added as a topping. These pizzas are baked right along with your regular thin crust pizzas, after baking they are cooled and sliced for sale by the slice. They are usually finished with the addition of a drizzle of string icing (powder sugar-water icing) after reheating for a few seconds for sale. Some even add a pre-bake topping of streusel which I personally think takes it to a higher level. These can be served cold, hot (reheated) or ala mode. There's a lot to be said for this type of dessert pizza, no matter how it's made. It sure beats dumping a can of pie filling on a crust and calling it a dessert pizza as many do!

[**Re: Berry tart pizza2204**](#)

Well, let's see if we can pick this apart a bit. You buy your dough from a local bakery, I'm assuming this is a retail bakery as opposed to a large wholesale bakery. I really can't think of many retail bakeries making "pizza" dough as a regular item unless it's by request or under contract so there is an excellent probability that what you are getting for dough is some type of bread dough rather than a formulated pizza dough, if this is the case, do you know what type of bread dough you're getting? Many bread doughs are formulated quite differently from pizza dough. Additionally, bread dough is fermented MUCH LESS than what we would typically ferment a pizza dough....hours as compared to days. It is this fermentation that is responsible for essentially all of the flavor we taste in a baked pizza crust, it is also responsible in a large part for the crispiness of the finished crust too. While you don't provide any information on baking your pizzas all I can say right now is that if indeed you are using some type of a bread formulated dough it might have more sugar than desired for the way you are baking your pizzas which would cause you to short bake the pizzas (we bake pizzas to bottom color) which in turn give the crust a very thin layer of crispy dough on the bottom, if the dough is formulated as a pizza dough using little or no sugar one would need to bake the pizza longer to establish a desirable crust color which develops a thicker crispy layer on the bottom of the crust which in turn retains its crispiness for a longer time after being

removed from the oven, this is assuming you are placing the pizzas on a screen or rack as opposed to placing them onto a metal pan immediately after removal from the oven. Baking develops flavor in the crust too, the longer the crust/pizza can be baked the more flavor it will develop due to the denaturing of proteins during the baking process. Without more information this might all be construed as just speculation...we all know what happens when we "assume". :-D

[Re: I want pizza dough, not play-doh](#)**2205**

What kind of flour were you using? What was your finished dough temperature? How did you manage the dough? These are all questions that play an important part in answering the question you posed.

The flour should be a high protein flour such as All Trumps (14+% protein content). The finished dough temperature should be targeted for 75F.

Dough management should look something like this: Mix, scale, ball, place in lightly oiled container (DO NOT COVER), after 3-hours cover the dough, cold ferment 24-hours, remove from fridge and allow to warm to 50 - 55F, (3-hours seems a bit long) open dough ball into a pizza skin for dressing and baking.

Let me know how it works for you.

[Re: Dough Doctor New York Pizza Recipe Issue](#)**2206**

Have you tried any of the Stanislaus products? Their 7/11 Ground Tomatoes with a little fresh or roasted garlic and fresh basil added to the sauced skin is one of my favorites after nothing but thin sliced vine ripened tomatoes (brush the skin with olive oil add the garlic and fresh basil then lay the slices of fresh tomato over the skin in place of a conventional sauce...excellent flavor, my all time favorite, but that's just me. Sometimes simple is the best.

[Re: Looking for thin crust sauce recipes](#)**2207**

What, if any, experience you have in the pizza/restaurant or food industry?

[Re: At ground zero - thinking of doing a thing - might need sense talked into me.](#)**2208**

Can you provide any pictures?

[Re: Tripoli's or Cristy's style dough](#)**2209**

Here is a pretty typical deep-dish dough formula:

Flour: 100% (bread type flour with 11.2 to 12.5% protein content)

Salt: 1.75%

Sugar: 2%

Shortening: 4% (Butter flavored Crisco works well)

IDY: 0.4%

Water: 62%

Target finished dough temperature: 75F.

add water to bowl first then flour and all remaining ingredients.

Mix to a smooth dough consistency (about 8 to 10-minutes).

Scale, ball and box the dough, wipe the top of the dough balls with oil.

Cross-stack in the cooler for 3-hours assuming 14 to 16-ounce dough balls for 12-inch pizzas.

Down-stack and allow to ferment for 36 to 48-hours.

Remove dough from cooler and allow to warm AT room temperature until internal dough ball temperature reaches 50F.

Using a rolling or pastry pin, roll out to a size just a little larger than the pan.

Fit the opened skin into an oiled pan and set aside to proof for 60 to 75-minutes. After 45-minutes check the dough in the pan and stretch to fit the pan if necessary. After dough has proofed you can use your fingers to form an edge by pulling dough up on the side of the pan or leave it as it is. Then add sauce and dress to the order. If using a deck oven bake the pizzas with a screen under the pan to prevent burning the bottom.

You will need to experiment with the amount of dough used in the pan to determine the thickness of finished pizza you want to have.

Cut finished pizzas using a rocker knife.

[Re: NY Style vs Spongy Pan Pizza](#) **2210**

208F is about as hot as you can get the internals and still call it bread. After that the temp rises due to loss of evaporative cooling (crumb drying out) and things begin to appear more like melba than bread....DoouBall nailed it!

[Re: Optimal temperature of cooked pizza crust?](#) **2211**

Try this:

Immediately after mixing scale and ball the dough, box, lightly oil the top of the dough balls, cross-stack (leave container open) and place in the fridge. After 3-hours down-stack (cover) and allow to cold ferment for 24 to 48-hours. Remove from fridge/cooler and allow to temper AT room temperature until 50F then do your magic and open the ball into a skin. Let me know how this works for you.

[Re: dough too soft, need advice](#) **2212**

Godfather's uses a "cutter" pan having 40 degree angles sides designed for cutting the dough into the pan. In Chicago they bake the thin crust pizzas directly on the deck using bakery type reel ovens.

[Re: High protein flour.](#) **2213**

I usually just make my own. Put a couple bulbs of garlic in the oven and roast until soft, cut the top off of each bulb and squeeze out the roasted garlic. I like to mix this into my home brewed basil pesto when I'm getting ready to dress a pizza.

[Re: Tessemae's Slow Roasted Garlic](#) **2214**

The KA flour should work just fine for you. Chicago style crusts are best made using a dough sheeter/dough roller, whatever you like to call it.

[Re: High protein flour.](#) **2215**

Deer heart pate anyone? ;D

[Re: Ruger American Rifle Vortex Scope Package](#) **2216**

Chicago thin is typically made using Ceresota flour (about 11.7% protein content) while N.Y. style is typically made using All Trumps flour (about 14.2% protein content). Chicago style is edge to edge while New York style has an exposed raised edge. Also, Chicago style is party cut while New York style in pie cut.

[Re: High protein flour.](#) **2217**

Actually, I've done it before. I used a (8-inch) pizza screen under the pizza and a 2" deep aluminum pizza pan (with a few nail holes in the bottom) inverted over the pizza for top heat. I put a small wood drawer pull on top of the pan for ease of removal. Not the best pizza but no one refuse to eat it! We also had a stove top oven made from a large popcorn tin. I used a .22 to shoot two holes across the

diameter of the can about 2/3 of the way up from the bottom, ran wire through the holes to create a shelf for holding an 8" cake pan. I flared the edges of the lid with a rock so the lid would just lay over the top. We used both for many years making camp pizzas and cakes for dessert....earned me the nick name "Camp Momma".

[**Re: Ruger American Rifle Vortex Scope Package2218**](#)

When applying mineral oil to my peels I've always put the oil onto a cloth towel and rubbed it in. You don't want to oil soak the wood as that would affect the way the wood releases the dough but you just want to seal the surface so go light and rub it in well, then burnish it by rubbing again with a clean, dry towel as if you are trying to rub off the oil that you just applied.

[**Re: Looking after a wooden peel2219**](#)

One thing that comes to mind is have you considered baking on a pizza screen rather than directly on the steel hearth? The screen will allow you to bake the pizza longer without getting excessive bottom crust color. You might want to use a higher rack position to control the top bake as the top of the oven will be hotter than the bottom. If in doing this you find that you want more bottom crust color then add a percent or more sugar to the dough formula to enhance bottom crust color development.

[**Re: Making pizza in bottom heating oven2220**](#)

2% for the trained person.

[**Re: Testing for absorption 2221**](#)

Never, ever wash a wood peel unless you are fond of a warped peel. If it needs cleaning just wipe it down with a damp towel. To maintain your peel periodically wipe it down with a light coating of mineral oil to help keep the surface sealed. If it gets rough sand it lightly with 200-grit sand paper and re-treat with mineral oil. Use your wood peel only as a prep-peel, prep the pizzas on the peel and peel them into the oven, then use a metal blade peel to remove the pizzas from the oven. I've had wood peels last me over 20-years with a little care.

[**Re: Looking after a wooden peel2222**](#)

It's not the quality of the flour where the issue is at, while it indeed does vary, and depending upon the year and circumstances sometimes considerably, at most all we ever see is a 1 or 2% variation and that's well within our level of tolerance for a pizza dough. Where things begin to go off in a different direction is when we begin seeing on-site (farm) stored wheat getting introduced into the grist over which the mill has no control. This grain can be up to 2-years in storage and in many cases has been stored under warm conditions both of which contribute to oxidized grain. What does this mean? It means that the flour performs as it it has been given an overdose of oxidation. When I was working at AIB I used to get calls from bakers all the time just a couple of weeks prior to the new wheat crop coming in. It seems that farmers were selling of their stored grain to make room for the new crop (part of which they would store on-site waiting for a better price as the price is always lowest right at harvest time). Additionally, bagged flour is prone to drying out too. When flour leaves the mill it is around 13 to just under 14% moisture but under certain storage conditions it can dry down to about 10.5%, when combined with normal flour absorption variations, if the planets are aligned correctly, you could see a variation in dough absorption of as much as 5% which you would see even in a pizza dough. I've dealt with a lot of calls from operators complaining that while

they have done nothing different, the dough is difficult to open or exhibits excessive memory characteristics since they got their last flour delivery. In almost every case I tell them to increase the dough absorption by 3% to see if that helps. It does help when the issue is due to drying of the flour but when it's due to oxidation of the wheat prior to milling we usually have to give the dough more fermentation or include a little reducing agent (dead yeast or PZ-44) in the dough formulation but then watch the dough VERY carefully because as soon as the mill works through the on-site stored grain (almost always within 3 to 4-weeks) the situation will immediately reverse itself. This is so bad in the wholesale baking industry (which includes commissary pizza) that companies have developed strategies for coping with what is called new crop transition which usually include a contracted blending of new crop with old crop or some just go "cold turkey" by cancelling all leave for senior supervisors and getting all new crop flour in their next delivery. With a little luck they normally sort things out in a day or two and life returns to normal for the better part of a year, then the cycle repeats itself.

[Re: Testing for absorption 2223](#)

Rats!!! Don't you just hate it when that happens? :-D

[Re: Testing for absorption 2224](#)

It would be nice if there was some way to do it but in order to even be remotely accurate you would need some way to accurately measure dough viscosity, which reminds me, there is another way...the Mixograph. This instrument incorporates a pin type mixer mounted on a spring loaded platform, during mixing the resistance from the pins on the mixer head forces the dough over the fixed pins in the bowl and this resistance causes the bowl to want to rotate, this force is recorded by means of a pen and chart allowing one to see maximum resistance (force). By this method water is added so maximum force is achieved within a specific period of time, then the absorption calculated, a factor between Mixograph and actual bowl absorption still needs to be developed just like the Farinograph. Haven't priced a Mixograph in many years but considerably cheaper than a Farinograph. Still figure on several thousand dollars.

OK, I'm really going out on a pretty thin limb here but here's an idea if you're really that bored and need something to do.

Get 5 or more plastic glasses (between 3 and 4-inches across the top), put varying amounts of water in each glass, add an accurately measured 100-grams of flour to each glass and using a stirring stick stir each glass the same (as close as possible), lightly cover each glass with a piece of foil to prevent drying, allow to set for at least an hour (time to be determined) as you want the flour to fully hydrate on its own. Glue a large marble onto a piece of strong thread, carefully lower the marble onto the surface of the dough and measure the length of time it takes for the marble to fully sink into the dough (set a 2-minute time limit for this to happen). Increase absorption until you get this effect. Calculate the flour absorption (water weight divided by flour weight X 100). So now you can say that you need to add sufficient water to the dough so the marble Fully sinks (until JUST submerged) this is important as it is a constant. and then you need to make a pizza dough using that same flour to find your "dough absorption", now just divide the dough absorption by the flour absorption to get the desired absorption factor for your SPECIFIC pizza dough formula and procedure.

Example:

100-grams of flour.

80-grams of water (80F MUST BE A CONSTANT TEMPERATURE) added to sink the marble.

80 divided by 100 X 100 = 80% flour absorption.

Your pizza dough was best when made with 60% absorption.

Divide 60% by 80% and you get an absorption factor of 0.75

Using the ABSORPTION FACTOR:

Find the new flour absorption %.

Multiply that by 0.75 to find the dough absorption needed to make your dough using that flour, in this case $0.75 \times$ flour absorption = the percent dough absorption needed for your specific dough.

Be aware that, even when using the best instrumentation, the absorption factor is only accurate to +/- 2%. That's the best you can hope for.

[Re: Testing for absorption 2225](#)

How is the spiral mixer a problem? ??? If you replace ADY with IDY be sure to use the correct conversion or you will be using too much IDY.

I'm on the program twice this year at Pizza Expo. One of my sessions should be very informative as it will be a 4-hour session allowing time for a lot of personal attention to problem solving and answering questions.

[Re: ADY to prove or not 2226](#)

Yes there is, the instrument is called a Farinograph and for a mere \$40,000.00 you can have one too. :D

Aside from that, I'm afraid the answer is no, I'm not aware of any other real method for measuring the absorption properties of flour out side of an analytical lab using NIR (near infrared). This is what I was doing when I retired from AIB, working with Dr. Rick Dempster using NIR to measure flour absorption.

In truth, the optimum dough absorption is that which provides you with the best compromise in dough handling properties while giving the best (desired) finished product characteristics, and since there are so many different ways of making pizza and so many finished product expectations, even if you knew what the flour absorption was you would still need to develop an absorption factor to convert the flour absorption into a dough absorption that you could use in your dough formulation.

By the way, the big users of flour (bulk, like in tank car loads direct from the flour mill) receive an analytical report on each flour delivery which also includes complete Farinograph data on that specific flour. This data is important as it allows them to make changes to their process or dough absorption to accommodate shifts in flour quality or more commonly flour absorption properties. As I've said so many times before, flour is probably the single most variable ingredient we work with.

[Re: Testing for absorption 2227](#)

As many of you are aware much of the U.S. is in the grip of a Polar Vortex with frigid temperatures and high winds, while here in Manhattan Kansas we don't have the really frigid temps YET (they're still coming) I decided to make a large pot of venison chili. The house is smelling great! :drool: It'll be ready by dinner time.

Nothing beats free range, organic, no hormones added venison, especially when I hunted it, harvested it, field dressed it, brought it out of the field and home, cut it into steaks, roasts, stew meat, fajita meat, hamburger (ground venison) and jerky strips, then enjoy all the fruits of your labor with a great meal while recalling another successful hunt.....it's as good as pizza! :)

[Re: Ruger American Rifle Vortex Scope Package 2228](#)

In one word....yes.

When not placed into a small amount of warm (95 to 100F) water to hydrate/activate some of the plasma material is leached out of the ADY which poses two problems, one the yeast cells, while still alive do not participate in the fermentation process and two, the material leached out of the yeast cells is glutathione, the exact same material that the reducing agent "dead yeast" is comprised of. This means that the glutathione exerts a softening effect or weakening effect upon the dough much like dead yeast or a similar product based on L-cysteine (PZ-44). In any case there is no way to tell how sever this might be so the end result is an inconsistent dough at best. IDY, on the other hand is designed to hydrate very quickly (hence the word INSTANT in its name) which allows the IDY to quickly absorb water and seal the fissures in the cell walls thus preventing loss of glutathione from the individual yeast cells. This can be an issue for IDY at the same time, if IDY is placed into water that is just 5F too cold (90F) if it is suspended for hand mixing, the cooler water will exert a flushing action (enter into the cells and back out again before the cell walls can seal so you get what we call a flushing action where the water leaving the cells brings the glutathione out with it.

[Re: ADY to prove or not](#)2229

We make the dough and sauce as well as prep the cheese if necessary at the main store which we use as a commissary. The dough is mixed, scaled, balled and boxed or bagged, cross-stacked in the cooler for 3-hours then down stacked. Once down-stacked the dough is held for 18 to 24-hours before being transported to the other store either in the early morning or in the evening/night time hours, it is placed directly into the stores cooler for use as soon as needed. If you do your part the dough is good for 2 to 3-days. A van is the easiest way to transport the dough to the second store. This method gives you MUCH better control over the dough and saves money as you don't need to buy more equipment making the dough or inventory ingredients at the second store, the big bonus is that you always have the same people making the dough so you are reducing the risk of something going wrong....like that never happens :D

The concept is very simple, this is how most kiosk stores operate as well as every one of the big box chain stores.

[Re: Growth Challenges from 1 to 2 shops](#)2230

I see that it's a whole white wheat flour. If the flour appeared to be fine (almost like a regular white flour) you may not see a whole lot of difference in the crust if you use it at about 25 to 30% of the total flour blend. The typical absorption for that type of flour is usually around 70%. Both dough performance as well as flavor suffer greatly if the absorption is too low.

[Re: High protein flour.](#) 2231

Can you send a picture of the label on the flour bag/package? There are different types of whole-wheat flour so it would help to get a better idea of which one you have. There can be problems with dough absorption when using some types of whole-wheat flour so if you find that after the fermentation period the dough has become very tight/stiff you know that it's due to insufficient absorption for the flour you're using. When referencing the protein content of the flour we are always referring to the gluten forming proteins (whole-wheat flour is about 1% higher in protein content but that additional 1% protein is not a gluten forming protein). If you make a pizza crust from your whole-wheat flour you will be making a whole-wheat crust, not bad, just different. If you blend it with white flour (2/3 white flour and 1/3 whole-wheat flour or dough), you will be making a wheat crust, again, different but not bad. There has been a lot of discussion here on using whole-wheat

flours if you want to look back in the archives.

[Re: High protein flour. 2232](#)

Sounds about right to me. After you remove the dough from the mixer it is no longer under tension from being worked by the dough agitator (hook/arm) so it quickly relaxes. It even does this to a great extent when still in the mixing bowl after the mixer has stopped. This is perfectly normal.

[Re: how fast?2233](#)

The KA mixers are just not up to the abuse of constant everyday use in mixing rather tough pizza doughs. I would highly encourage you to look into at least a planetary 20-quart mixer or better yet, one of the 20-quart spiral mixers. Eurodib makes a 20-quart spiral mixer that sells for \$1,100.00 or about half of what a planetary mixer of the same size sells for and it should last you for a very long time. The main thing when mixing the dough is to mix it faster than slow speed just until you achieve a smooth appearing dough.

[Re: Developing Midwest Thin for commercial use2234](#)

With exception to *Bacillus Mesentericus* (Rope) spores, bread is essentially sterile when it comes out of the oven. Rope is not a dangerous organism it just gives the bread a funky nail polish remover or over ripe cantaloupe aroma.

[Re: Room Temperature Fermentation Safety?2235](#)

Aside from a few recent recalls (Mark IV and American Pistol) I can't think of any issues with Ruger products over the past 40-years. My favorite deer rifles are a #1 in 45/70 and a Hawkeye in .338 Federal. I've probably got half a dozen or more Rugers in the safe and they all get a lot of range time and none have ever given me any issues what so ever, I'm sure a few bad ones have gotten out but nothing any worse than from any other manufacturer.

[Re: Ruger American Rifle Vortex Scope Package2236](#)

From a commercial standpoint the dough is going to be really tough to roll out using a rolling or pastry pin. Since this is for a commercial operation my advice is to spring for a dough sheeter/roller, otherwise you will be wasting a lot of time in opening the skins.

Here's a good formula to start with:

Flour: 12.2 to 12.8% protein content 100%

Salt: 2%

Oil: 4%

IDY: 0.7%

Water: 50 to 54%

Targeted finished dough temperature: 80F

Mix to a "just" smooth consistency (about 8-minutes) at medium speed.

Scale and ball immediately after mixing.

Place in dough boxes, wipe with oil.

Cross-stack in the cooler for 2-hours then down-stack.

Cold Ferment for 18 to 24-hours.

For a trailer or truck:

Allow dough to warm at ambient for 1-hour prior to opening the balls into skins.

Place skins on pizza screens and hold in a wire tree rack for up to 20-minutes.

To use the dough from the tree rack invert the skin onto a peel or pan with a light

dusting of corn meal.

Dock the skin.

Sauce and dress to the order and bake.

[Re: Developing Midwest Thin for commercial use](#)2237

I just find that it is easier to answer a question if I know specifically what pizza is being discussed. When I was at AIB we did some work baking this style of pizza in the Lincoln air impingement oven with moderate success as compared to a deck oven. I don't remember all of the specific details anymore but I do remember that we had to play quite a bit with both the top and bottom finger profiles since a "regular" pizza profile did not work well, that's about par for the course and it's why they have so many custom fingers for those ovens as it allows one to set-up the oven for very specific baking applications. The down side is that you now have a pretty dedicated oven which may or may not work well with other products which need to be baked in a pizzeria setting. Most typical "pizza" finger configurations are sufficiently versatile so they have a broad application in baking other menu items such as garlic knots, bread sticks, calzones, wings, etc. If you are interested in further exploring this option find an air impingement oven manufacturer close to you or one that you have a preference for and discuss the possibility of doing a few test bakes at their facility to assess the feasibility.

[Re: ROMAN style dough and the Impinger oven](#)2238

Go with Nosler Partition bullets or commercially loaded rounds using them or any of the monolithic bullets like those made by Barnes or Hornady for the tougher stuff and regular cup and core bullets (150-grain weight) for anything else, if your shots will be out at 200+ yards any of the lower cost 130-grain cup and core bullets will work fine. If you must use the 130-grain loads and your range will be less than 150 to 200-yards just remember to pick out the end you want to eat then shoot the other end. Those 130-grain cup and core bullets are just plain too explosive when driven at 3,000+ fps and the range is close. By hand loading though you can load them down to 2,600 to 2700 fps and they perform well out to 250-yards on deer size game.

[Re: Ruger American Rifle Vortex Scope Package](#)2239

I have one in 30/06 and I can't slight it in the least. Trigger is great for a production rifle (most are these days) and it's adjustable so you can set the trigger pull to where you like it. I also have a Ruger Ranch rifle in 7.62 X 39 which I'm quite fond of too. The Vortex scope presently sells for between \$150.00 to \$167.00 U.S. and add another \$20.00 for rings. The rifle comes with a rail so bases are not needed. The rifle retails here for about \$475.00 U.S. but we can pick them up for about \$100.00 less. I was just looking at what was essentially a new Ruger American Ranch Rifle in .223/5.56 with a scope, sling, extra magazine for \$450.00. The .270 Winchester is a fine caliber for deer size game and maybe a bit bigger with some of today's premium bullets out to about 400-yards if you can hold up your end of the bargain. I have a friend who uses a .270 for deer here in Kansas (bucks go 100 to 140 kgs. in weight). He used to use 130 grain bullets but at ranges we shoot here in Kansas (100 to 150-yards) they were overly destructive so he now uses only 150-grain bullets and eats more of his harvest.

[Re: Ruger American Rifle Vortex Scope Package](#)2240

To the contrary, commercial bakers yeast will acidify a dough quite nicely in just a few hours....not to sourdough levels of 4.0 and less but easily into the 4.5 to 5.0 range from a starting point of 6.8 to 7.0 pH. Mom would have poisoned all of us

kinds with her home made bread if it were not for this.

[Re: Room Temperature Fermentation Safety?2241](#)

Squash such as crooked neck or zucchini are great choices as for any watery vegetables you might have a concern about drain well and place in a clean towel to absorb excess moisture....don't over do it with the amount you add, ditto for the green and black olives, onions.

[Re: Toppings suggestions needed \(vegetarian\)2242](#)

- 1) Decide what dough weight you want to make.
- 2) Divide the dough weight by the sum of the bakers percent in your dough formula divided by 100.
- 3) This will give you the flour weight to make your dough of desired weight.
- 4) Then flour weight X ingredient percent you want the weight for, then press the "%" key and read the ingredient weight.

Remember that the ingredient weight will ALWAYS be in the same weight units that the flour weight is shown in.

[Re: recipe conversion from % to weight \(oz\)2243](#)

As long as you have yeast or some other desirable bacteria strain in the dough to accomplish acidification of the dough it is perfectly safe to ferment the dough at any temperature that will support fermentation

[Re: Room Temperature Fermentation Safety?2244](#)

When using the parchment paper you have two options, one is to just slide the pizza into the oven with the parchment paper under the skin and bake the pizza, removing the parchment paper when you remove the pizza from the oven, the other approach is to allow the pizza to bake on the parchment paper until you can slide easily your peel under the skin and remove the parchment paper allowing the pizza to finish baking right on the oven deck. Either way is OK.

[Re: Pizza Crust2245](#)

How much of a difference in diameter are we talking about? Up to about 1/2-inch is normal.

[Re: Shrinking Dough2246](#)

I'm from Chicago also, probably just a matter of taste.

[Re: Corn meal2247](#)

I'm not sure if I'm understanding your question correctly, but to the very best of my knowledge most, if not all of the New York style pizzas are made with white flour, with General Mills All Trumps (14+% protein content) being the most popular brand used. Possibly you heard "wheat flour" which would be correct in a general sense as opposed to whole-wheat flour which is an entirely different type of wheat flour as it contains approximately 20% bran.

[Re: Bread flour / whole wheat flour mix2248](#)

Sure, not a problem in dividing the water into two parts and dissolving the salt in one and suspending the yeast in the other. This is remotely similar to the way you would have to do it if you were using ADY (active dry yeast or IDY (instant dry yeast) and mixing the dough by hand.

[Re: Questions for a better understanding of the dough2249](#)

My first impression was that it was going to be an emergency type dough, we understand though. :)

[Re: This is my basic quick pizza dough2250](#)

To use the bags of flour you have in the freezer its best if you can remove what you will need to use the day before and just set it out on the counter to allow it to warm up. Extremely cold flour doesn't absorb water as quickly as warmer (room temperature) flour does. Not a big deal if you forget to take it out of the freezer just remember that the dough might feel a little different at first BUT also remember that the extremely cold (frozen) flour will also impact the finished dough temperature resulting in a colder than anticipated finished dough temperature unless you correct for this by using slightly warmer dough water. Probably easier to just remember to take it out of the freezer the day prior to use. :)

[Re: Flour Storage Products2251](#)

For a dough that'll be fermented that long you only need to mix the dough until it takes on a smooth appearance, biochemical gluten development will take care of the gluten development for you with a lot less wear and tear on your mixer, and it will shorten your process too while giving you a more open finished crumb structure in the crust. The "window pane" test really has little application in pizza making as pizza doughs are typically under mixed to help achieve the desired finished crust characteristics, where the window pane test is used to good advantage is in bread making (as in sandwich/loaf bread), in this case the dough is mixed to full gluten development and then even a little more to achieve the desired dough extensibility the result is a dough that produces a finished loaf with good volume and a close, tight knit crumb structure.

[Re: This is my basic quick pizza dough2252](#)

To answer your question #3, just use less dough...problem solved. If you were to proof it less the crumb structure would change as would the eating/mastication properties of the crust. By using a bit less dough and proofing it to the same time as you are proofing the full weight dough you will get a similar crumb structure but with less height/thickness. When we were making the PH type deep-dish pizzas we used a final proofing time of 70-minutes but that will change with your actual dough formulation as well as dough and room temperature.

As for your question #1, look at the thickness of the metal the pans are made from and buy the thicker/heavier pan as it will be more durable and provide for an overall better, more uniform bake. You might need to go to the respective web sites to get this information and remember that many times pans are offered in different thicknesses/weights so make sure you are comparing apples to apples. If the pans are bright metal, anodized or not, you will need to season them well prior to use.

[Re: PIZZA PANS2253](#)

If you are planning to store your flour for up to a year it will be better to store the flour, regardless of what it's stored in, in the coolest place possible. Ideally, under refrigerated temperature but if that's not possible for you revert back to "as cool as possible". In my experience, anything over 70F is too warm for long term flour storage.

[Re: Flour Storage Products2254](#)

Those are some mighty fine looking pizzas!!!

[Re: Help with recipe for long cold ferments2255](#)

The main reason for dissolving the salt in the water is for improved dispersion throughout the dough when the dough is NOT going to be mixed by machine. When using a dough mixer, unless a coarse granulation salt is being used, it is not necessary to dissolve the salt in the water so it can be added directly to the flour. The same is true for the yeast (compressed yeast) as it should be suspended in the dough water to ensure thorough dispersion throughout the dough when hand mixing is employed. When a dough mixer is used the compressed yeast can be crumbled right on top of the flour and the mixing agitator will do the rest for you. As for mixing the salt and yeast together, this is generally not a good idea as it can potentially harm the ability of the yeast to ferment. The salt can exert a greater osmotic pressure than the yeast so the salt can potentially pull the plasma material out of the yeast cells, not necessarily killing the yeast cells but definitely impairing their ability to participate in the fermentation process not to mention the fact that the plasma material will be glutathione, a dough reducing agent which can make doughs softer and more extensible. Dead yeast AKA glutathione is sold commercially as a consumer friendly dough reducing agent (dough softener). While incidental contact between salt and yeast in the water may not be harmful (direct contact between the two is) if you were to get distracted and allow some time between putting the two together in the water and adding the flour and mixing the dough you could get some inconsistencies in your dough that might cause you to add more or less water or thing that your mixing is off when all that happened was that you got distracted at a bad time.

[**Re: Questions for a better understanding of the dough**](#)**2256**

Jason;

Keep in mind that RT bulk fermentation will yield far different results than cold bulk fermentation within the same time frames. A lot will depend upon at what temperature your starter performs best at which is a function of the micro-flora present.

As for scaling and balling a bulk fermented dough, I like to scale and ball immediately after the bulk fermentation period. I do not recommend allowing a bulk dough to warm-up prior to balling as this will introduce a ball park of variables into the dough. The main one will be due to the outside of the dough warming while the inside remains cool (if you have it FULLY refrigerated with a core temperature of 40F or less). If you do the bulk fermentation at room temperature (not really recommended unless the RT is CONSTANT) you will need to experiment to determine when the dough has been sufficiently fermented to provide the flavor and performance characteristics desired. There is no real way to predict this so it will have to be determined through experimentation or trial and error. Keep good and complete notes as doughs made with SD starters tend to be much more responsive to times and temperatures. Consistency is the name of the game so don't be afraid to "A-Retentive" when doing your experimentation as it will help you stay on track in the long run.

[**Re: WHEN TO BALL DURING BULK FERMENT**](#)**2257**

Well put! Additionally, remember that hunger is triggered by a drop in blood sugar, so you pop a sugar cube, your blood sugar spikes and you're no longer hungry BUT soon that sugar is metabolized and your blood sugar once again drops, the process keeps repeating itself over and over again. This is actually pretty easy to demonstrate to yourself using sugar cubes or candy which is high in sugar (I don't recommend doing this if you are diabetic). I once had a lady tell me that she always got light headed when working out at the gym after work, I suggested that she eat

two slices of bread before she left work, the starches/carbs in the bread were slowly converted to sugars which could be metabolized thus maintaining her blood sugar at a reasonable level, end result.....she no longer complained of getting light headed during her work out and she also indicated that she was no longer hungry enough to "eat a horse" when she got home. It's called blood sugar management, something more of us should pay closer attention to.

[Re: Natural sugars in flour. Breaking down the Carbohydrates. How healthy is it?2258](#)

It's not for the weight, it's for the evaporative cooling it provides which reduces the temperature at the top of the skin (crust) thus reducing bubbling. Also be sure to dock the crust with a good (blunt) dough docker to further control any bubbling which might occur.

[Re: Freeze cooked vs uncooked2259](#)

The suggestion from Hanglow is the best one, the wood is much easier to cut the pizzas on and it will help to retain the heat in the pizzas. Aluminum is possibly the worst material to use as it conducts heat away from the pizza and it also results in condensation forming between the crust and the aluminum surface. A common solution is to buy a box of corrugated cardboard pizza circles, place the pizza circle on/in a pizza pan (a screen works well too and they're cheap) to provide rigidity to the pizza circle. Used in this manner the circle insulates the bottom of the pizza from the surface upon which it is placed so it stays hot a little better and doesn't contribute to condensation forming on the bottom of the pizza, the cardboard is also a good cutting surface.

[Re: Pizza Serving Plates2260](#)

I forgot to add, to par-bake your crusts use a temperature of 400F to 425F and bake on a seasoned pizza screen, if you will be baking on some type of a deck surface (stone or baking steel) you can par-bake at up to 500F. Remember, the object is to bake the skins JUST long enough to fully set the structure...no longer. The par-baked crusts will have a very light/ slight browning, no more than that. If you see what appear to be oil spots developing on the cooled crusts these are NOT oil spots, they are areas of dough collapse due to insufficient baking. To correct the condition you will need to bake the par-baked crusts a little longer (by little I mean maybe only 15 to 30-seconds). To do this without getting too much color or bubbles you might need to lower the baking temperature by 15 to 25F to allow for a longer bake time. In any case, if you encounter any problems let us know and we can guide you out of it.

[Re: Freeze cooked vs uncooked2261](#)

Folkpicker;

The SOP (standard operating procedure) for making frozen pizzas is to make them on a par-baked crust. Par-bake your skins using about 1/2 of the sauce on the skin to prevent bubbling, then place on a rack or screen to cool thoroughly, then apply the remainder of the sauce along with the cheese and other desired toppings, place on a pizza screen to allow for air circulation around the entire pizza and freeze for at least 3-hours, remove from the freezer, place onto a cardboard pizza circle and IMMEDIATELY wrap in stretch wrap. Wrap in at least two layers of stretch wrap and place back into the freezer. I can't say how long the pizzas will keep in your freezers but I'm guessing you should be able to pull a pizza once a week for at least two months. To bake the pizzas always bake from frozen, place on a pizza pan or cookie sheet for baking at 400 to 425F until the cheese is hot and bubbly. You may

need to experiment with the baking time and temperature a little but this should get you in the ball park. Remember to adjust the baking time and temperature to get the top side of the pizza baked properly if you find that the bottom needs more or less color adjust the bottom color by adding more or less sugar to the dough formula (more sugar for greater color and less sugar for a lighter or less color). If you like to have the edges (rim) with more color and everything else is OK just brush the edge of the pizza with olive oil just before you place it into the oven. For something a little different, try sprinkling on a little EVOO as soon as the pizza comes out of the oven (the temperature of the pizza will "pop" the flavor of the EVOO. Another trick is to sprinkle the top of the pizza with grated Parmesan cheese or a blend of Parmesan and Romano as soon as the pizza comes out of the oven. Lastly, brush the edge with EVOO before baking, then apply some shredded Parmesan cheese to rim (it won't hurt if you get it in the center too), in this presentation the cheese will melt and be toasted on the edge imparting a great toasted cheese flavor to the edge crust. This is just like they do when making the Bobloli Pizza Crusts that you can buy at the supermarket.

Have fun and experiment. By the way, my personal favorite is to brush the edge of the pizza with water and sprinkle with raw sesame seeds (not too heavy or they'll just fall off after baking), the seeds will be toasted during baking giving a great flavor to the edge crust.

[Re: Freeze cooked vs uncooked](#)2262

Here's my personal take on this;

There are just so many factors involved and capable of affecting the conversion from one type of yeast to another under real life dough conditions that all you need is to be close to a reasonable conversion, then adjust accordingly as previously mentioned. Remember, even the properties of your water can/will impact yeast performance properties. Be thankful we're making dough, not nitroglycerine. :-D

[Re: IDY, ADY, Cake Yeast Conversion Chart](#)2263

Peter;

You are absolutely correct about the issues when making a thin cracker type crust where you have to trim scrap dough away from the skin to achieve the desired finished diameter. At the time when we were working with cracker style thin crust pizzas we were looking at pizzeria applications only. The method that we developed was based only on the used of a mechanical dough sheeter/roller. We would use dough balls of increasing weight and open them (using the dough sheeter/roller) to a diameter about 2-inches greater than the desired finished diameter, dock the entire skin and place it onto a pizza screen of the desired finished diameter, using a bench scraper, trim off the excess dough, transfer the skin onto a dusted prep-peel and dress for baking, bake and ascertain the quality characteristics of the finished crust. This was done for each dough ball weight and the most desirable dough ball weight was selected. The roller settings were recorded as was the technique for passing the dough through the sheeter, with this done all the operators had to do was to scale the dough to the specified weight, set-up the sheeter correctly, pass the dough through the sheeting rolls in the prescribed manner, dock the skin, place the skin on a pizza screen of correct diameter and trim off the excess using a metal bench scraper, transfer the trimmed and docked skin to a dusted prep-peel, dress to the order and bake on the deck. In applications where an air impingement oven was used the sheeter and docked skin was placed directly onto the baking platform, trimmed, dressed and baked. The exception to this was when a cutter type pan was used (40-degree sides on the pan), in this case the dough was draped over the pan and fitted into the pan, a rolling pin or pastry pin was then rolled over

the top of the pan to crimp-cut the surplus dough from the pan after which it was dressed and baked. As for the scrap dough which was being generated, this method was developed to minimize the amount of scrap generation, the scrap was collected and used for "other" products like bread sticks, garlic knots, and cinnamon crisps (thin rolled dough, cut into 3-inch squares, brushed with water and sprinkled with a cinnamon-sugar mixture and baked until lightly browned, then drizzle with powdered sugar-water icing and serve as a dessert). We would also cut the skins into very thin strips and bake on a pan or screen as Grissini style bread sticks. Any scrap dough that was remaining at the end of the day would be re-incorporated into new dough at a rate not to exceed 15% of the total dough weight (about 12-pounds for a dough based on 50# of flour weight).

One of the later projects that we worked on was that of trying to develop a method where we would open a dough ball of fixed weight to a pre-determined diameter with no scrap generation at all (this was done at popular request by pizzerias as they didn't want to deal with the scrap dough being generated). My partner, Jeff Zeak demonstrated the procedure a couple of times at Pizza Expo (XLT Ovens booth) but for some reason it never really caught on, we attributed this to the growing popularity of the Neapolitan style pizzas. All part of the evolution of PIZZA.

[Re: Correctly gauging TF](#)**2264**

I should also add that in the literature provided by the yeast manufacturers they do indicate a 3 to 1 ratio for CY to IDY but this is just a little on the conservative side, maybe they just rounded things to the nearest point where it would be easy to remember the conversion, or maybe it sweetens the pot a little for making a change to IDY from CY, whatever the reason, the 3 to 1 ratio works OK in home applications and probably most pizzeria applications but not so well in applications where we need to be A-Retentive in proof times and total gassing power and don't have a lot of flexibility in changing the dough parameters.

When it comes to yeast (regardless of the type), I think it's best to start with a specific recommended amount but then because of differences in dough formulation and dough management procedures, and expectations/personal preference, adjust the yeast level to give you the best product possible.

[Re: IDY, ADY, Cake Yeast Conversion Chart](#)**2265**

Michael;

When you say "Roman" dough are you referring to Neapolitan pizza dough?

[Re: ROMAN style dough and the Impinger oven](#)**2266**

As Peter correctly mentioned, there is no hard and fast conversion in the "real" world but if you contact Lesaffre Yeast Corporation<www.lesaffreyeastcorp.com> you can get a copy of their "Directions for Use Guide for Instant Yeast" which also covers Active Dry Yeast on the reverse side. The guide references recommended amounts of IDY/ADY against CY.

In work that we did at AIB using instrumentation to measure the gassing power of the different types of yeast (ADY/IDY/CY) we found the following: To replace one part (1%) CY we actually needed to use 0.375% IDY or 0.5% ADY. The water addition mentioned was not necessary in the "real world" until the amount of dry yeast got up to a total weight of 4-ounces or more if you are using IDY or ADY exclusively you will "auto-correct" the dough absorption in the end so it's really not something to be concerned about. It's only a concern the first time you make a change in yeast types and large size doughs are involved.

Also as stated, the dough formulation can play a big role in the yeast conversion

too with salt and sugar levels impacting the end conversion rate to some extent. The biggest "fly in the ointment" is the age of the CY as it continues to deteriorate with age and is highly impacted by storage conditions....in other words, it's highly perishable. In commercial bakery applications CY deliveries are received at least twice a week and typically used within 48 to 72-hours of receipt. It is temperature checked at the time of receipt and maintained under refrigeration right up until the time it's added to the mixer. All of this is required because the yeast sets the stage for the final proofing time for baked bread or the shelf-life of frozen dough both of which are CRITICAL in these applications. In pizzeria applications proofing is not the norm and when it is incorporated into the pizza making process (such as when making pan/deep-dish pizza) the time is not critical as automated proofing/baking systems (such as a serpentine proof and bake system) is not used as is common in the baking industry. The same can be said for home pizza making and even home bread making where if the dough feels or performs a little different it's easy to compensate for and if the dough requires a few minutes additional proofing time it's not a big deal.....try convincing a commercial bakery or frozen dough manufacturer of that! :-D

[Re: IDY, ADY, Cake Yeast Conversion Chart](#)**2267**

I'd say you will want to practice your dough opening technique to get a more round shape to your pizzas. You might try this for starters, use a rolling pin or pastry pin to PARTIALLY open the dough ball (about 50mm) from the desired diameter, then finish opening the dough by hand to full diameter. The color of the crust with 2% sugar actually looks quite good, what does the bottom of the crust look like? When baking pizzas on the deck we bake the pizzas until the bottom of the pizza is done (this is called baking to the bottom crust color) so if you want to get a darker overall color you can either lower the baking temperature to around 274C or bake the pizzas on a seasoned pizza screen, then "deck" the pizzas for the last 30-seconds prior to removing from the oven. Either of these should give a stronger top color.

[Re: Help with recipe for long cold ferments](#)**2268**

The 7/11 Ground Tomatoes is my "go to" base for most of my sauces, just add a little fresh basil and garlic to the sauce after applying it to the skin, then the cheese and dress to the order. For my upscale pizzas I like to use the 74/40 Tomato Filets (drained for 20-minutes), lightly oil the skin with EVOO, add fresh basil and garlic and apply the tomato filets instead of a spreading sauce. Flavor and texture are great, second only to fresh, vine ripened tomato slices.

[Re: Full Red with Basil \(Unprepared\)](#)**2269**

There ya go!

What was the concern over black pepper again? :-D

[Re: Adding black pepper to dough - any issues?](#)**2270**

Define "way over risen". Did the dough rise and then collapse all on its own? That's a pretty good definition of over risen since in that case the dough has become so weak that it can no longer support its own weight (re-ball may or may not salvage a dough that has over risen aka over fermented). If your dough just kept gradually rising without collapsing (you didn't mention anything about the dough collapsing) fermentation is most likely the issue. If you have a true SD based on a lactic acid forming bacteria it can easily take 18 to 24-hours for the dough to become properly fermented. We used to allow our SD rolls to final proof for 18-hours between forming and baking.

[Re: When is the dough ready to bake?2271](#)

It sounds like your dough isn't getting enough fermentation for your specific taste. Try increasing the amount of SD culture but continue using your regular procedure.

[Re: When is the dough ready to bake?2272](#)

Spot-on! :).

[Re: NY style dough help2273](#)

For me, I find a wood surface is the best for opening skins. I've got a laminated 2-inch thick maple cutting block that I use, it's heavy enough to stay put and I just stand it up at the end of the counter when not in use.

[Re: Cheapest way to obtain a stainless steel stretching surface?2274](#)

Malt, at VERY low levels, such as normally malted flour is not a problem with pita due to the short fermentation time employed. Adding sugar or greater amounts of malt will result in the center (silver dollar size brown spot) of the pita getting too dark or burnt, which results in it cracking upon cooling or rolling in use. When correctly baked you can cut the pita in half and see an equal amount of crumb structure on both the top and bottom of the pita. You can make something that pockets like a pita at a much lower temperature (we see this happening with pizza occasionally) but all of the crumb will be located on only one side with the other side being very thin which quickly leads to a brittle or dry pita.

By the way, one trick that I developed a number of years ago for making a better pita is to spray the pitas with water IMMEDIATELY after they come out of the oven (this will collapse the pocket and limit moisture loss making for a softer pita) as soon as the pocket is collapsed flip it over and repeat on the other side, cool on a rack for about 15-minutes, package at 110F. DO NOT REFRIGERATE OR FREEZE. If you absolutely must refrigerate or freeze do not do so until after the pitas have thoroughly cooler in the package (about 3-hours). Neither refrigeration nor freezing does anything good for a pita except to accelerate the staling process. So why are commercial pitas frozen? For marketing/distribution....nothing more.

[Re: Low Carb Pita bread, can it be done??2275](#)

TMB;

Make sure you use/specify "whole" white wheat flour as it can also be had as a patent or straight grade flour which means it is then just like any other white flour but it is milled from varieties of hard white wheat. All of the flour milled in Australia is made from hard white wheat varieties. This is done since when using hard white wheat as opposed to hard red wheat they can get a longer extraction (more pounds of white flour per 100-pounds of wheat). If I remember correctly in Australia their extraction rate is around 83% while here in the U.S. using hard red wheat the extraction rate is about 78 to 80%. That's a HUGE difference when you consider the amount of wheat a typical flour mill processes in a single day.

Also, did you ever see that the word "bread" is not always placed after "pita"? The reason for this is because in the CFR (code of Federal Regulations) there is a definition for "bread", if I remember correctly the product must have a weight of 12-ounces or more to be called bread. This is why the correct term is "pita" or a package of "pitas". So why do you still see "bread" tacked on to "pita"? While it's still not correct or even legal it is in such wide spread use I think they just turn a blind eye to the issue or they will until someone begins complaining, that's when enforcement kicks in. Be glad you're not a wholesale food manufacturer where you

have to know and abide by each and every one of the local, state and Federal laws regarding how you make something, what you put into it, how you label it, what you call it and where you place the information on the package and the print size too, oh yes, they even tell you how to run your business!

Ain't the food industry great? :)

[Re: Low Carb Pita bread, can it be done??](#)**2276**

You're right about the regs for the maximum number of insect parts (not whole insects) allowable per pound of product. I used to run the entomology lab during my early years at AIB back when we were located in Chicago, Illinois.

[Re: Adding black pepper to dough - any issues?](#)**2277**

Great advice from all! I'll try to add a little if I can. I'd suggest blooming/activating /hydrating the ADY in water at 100 to 105F rather than 80F which is still a bit too cold. Are you leaving the dough ball containers open or are you closing them right away when you place them in the fridge? As for getting ready to open the dough balls, allow the dough balls to come to at least 50F at room temperature before you try to open them into skins. You will want to experiment a bit in this regard and try 50F, 55F, and 60F to see what works best for you. Mind you, these are all internal dough ball temperatures we're talking about here, not surface temperatures so you'll need to poke them with a stem type thermometer. Also, do an absorption series on your dough where you incrementally increase the dough absorption in 2% increments. 62% dough absorption might be a bit on the low side to achieve the open crumb structure you're looking for. Additionally, you say you want to have a softer crust, the addition of oil as suggested will help as will the higher dough absorption as it will provide for better bake-out of the crust which will make the crust eat more tender, some might equate this to being softer, and lastly, you might even want to look at increasing the dough ball weight as a slightly thicker crust will naturally tend to be softer than a thinner crust with all things equal.

[Re: Help with recipe for long cold ferments](#)**2278**

Interesting thing, back when I had that CCC contract the Government did cut back on their subsidies of dairy products BUT the new plan was based on the number of cows being milked. Yup, beef prices dropped at the supermarket as the dairy farmers thinned their herds, what happened next was to be expected. Dairy farmers got rid of their poorer milk producers and kept the highest volume producers, and so it went.....now all of their milk cows were producing more milk than the larger herd was previously.....back to square one, whoda seen that one coming?

[Re: 1.4 BILLION Pound Cheese Surplus!!!!](#)**2279**

If you have a Habitat For Humanity Restore near you be sure to check them out too. We have one by us and I'm regularly there looking for a solution to a challenge. They regularly have stainless steel sinks with stainless drain boards in their collection of sinks, faucet sets, and toilets. If the piece isn't too big for the price of a SS sink (\$15 to \$40.00) you could cut the drain board out with an angle grinder and glue it to a backer board. Just a thought.

[Re: Cheapest way to obtain a stainless steel stretching surface?](#)**2280**

We once had a director in our Food Safety Group at AIB who stated "If it wasn't for the oven bakers would have poisoned mankind many thousands of years ago". He might have had a point there. For the most part though, aside from the optics, eating confused flour beetles, cigarette beetles or Indian meal moth larvae isn't

going to make you sick, and once they've been processed through the oven they're pretty sterile (204 to 208F). Many years ago WHO (World Health Organization) did a study on an African village where the locals were losing a lot of their grain to insect infestation as it was stored in clay (sorta like adobe) grain storage silos....more like a hut. WHO replaced all of the clay silos with new, modern metal grain storage silos (10-feet high, like you regularly see today on farms for on-site grain storage) and within months of getting their new silos the children in that village were beginning to show signs of protein deficiency...Why you ask? Because their diet was already deficient in protein but the insects that they were eating with the grain kept them above the threshold for deficiency and when those insects were deleted from their diet they began to show signs of protein deficiency, so yes, there is a lot to be said about the protein contribution of the insects.

One other thing about the pepper bread, if you don't want the black specks from the pepper just use white pepper...problem solved.

[Re: Adding black pepper to dough - any issues?2281](#)

No, they are not. Get some food saver bags from your local supermarket or in a pinch I've actually used the plastic Walmart bags (you didn't hear that from me). Twist the open end into a pony tail to close and tuck the pony tail under the dough ball as you place it in the fridge. This method allows the bag to give a little to accommodate expansion of the dough ball without tearing or popping open. Be sure to check those Walmart bags first for any tears or open seams.

[Re: NY style dough help2282](#)

We used to do it all the time with our potato bread, black pepper and potato go together like a hand in a glove. I can't say how much to use since the flavor of black pepper is literally all over the board potency wise. A good starting point would be 0.25%.

[Re: Adding black pepper to dough - any issues?2283](#)

To me, those dough balls look like they're ready to be used, like now. I'd say to go ahead and re-ball them. As for your fridge, try using plastic bags (bread bags) the next time, the plastic bag procedure is great for use in a small fridge since there is no cross-stacking required.

[Re: NY style dough help2284](#)

A good number of years ago I had a contract with the CCC/USDA (Commodity Credit Assn.) which required me to travel across the U.S. for several months showing schools and prisons how to utilize more cheese in the products which they were making. Most of the cheese going into Government storage is a cheddar cheese but there is also a fair amount of dry milk going into storage too. This is all in the form of whole milk solids which has not been heat treated aka high heat dry milk solids, the milk is not high heat treated so it can be further processed into cheese at a later date. If the milk is high heat treated it cannot be processed into cheese. The sticker though is that the manufacturers do not always mark the bags to identify them as being high heat treated (bakery grade) or not.....go figure! For this reason most of the dry milk solids in storage end up going into drinks and cake production but not yeast raised products as the non high heat treated milk solids will have a softening/weakening effect upon the dough. I mention this because the Government will probably be trying to reduce its dairy commodity inventory once again and some visitors to this site may find it available to them for use. When I had my contract with the CCC I was also working with pizzerias that made pizzas for schools and I was showing them how to include cheddar cheese into the school

pizzas. In this case the schools would provide the cheddar cheese to the pizzeria in 5# bricks and they would grind/shred the cheese for use on the pizzas they were making for the school to help keep the costs down. More recently I've been working with university dining services helping them do the same thing but in-house.

The politics behind this stuff is mind boggling too.

[Re: 1.4 BILLION Pound Cheese Surplus!!!!2285](#)

When machine mixing I just add the water and then the flour on top of that followed by the dry ingredients and begin mixing. I always add the oil late (delayed oil addition mixing method). One variation to this when hand mixing is to put the salt and sugar (if used) into the water, then add the yeast in suspension immediately followed by the flour, the oil is added after a couple minutes of mixing.

[Re: Gradual addition of flour?2286](#)

How big of a piece are you thinking about?

[Re: Cheapest way to obtain a stainless steel stretching surface?2287](#)

Here is a very traditional pita formula:

Flour: 100% (any bread flour will work fine)

Salt: 1%

Oil: 1%

Yeast: (CY: 1%) or (ADY: 0.5%) or (IDY: 0.375%)

Water: 50%

Mix to a smooth dough (80F)

Bulk ferment 1-hour.

Scale and ball.

Allow dough balls to rest for 20-minutes.

Sheet to size.

Bake.

Remember; A good pita is baked at 800F+ with a baking time of not more than 28-seconds.

[Re: Pita bread2288](#)

Just my opinion, but that seems like a lot of fermentation for Caputo.

Try cutting it back to 18-hours to see if the dough performs any better.

[Re: Help with Dough Issues2289](#)

Josh;

When balling the dough the tightness of the ball will, to some extent, control how much the dough ball will spread out during the fermentation period. To some, who like to have a very round dough ball for opening, a tighter ball is better while if you're proficient at opening the dough you don't need to round the dough as tightly. The mantra when rounding the dough should be CONSISTENCY, CONSISTENCY, CONSISTENCY. By placing the dough ball with the seam side down helps to ensure that the dough seam holds and remains intact. This is the same reason why we place moulded bread dough in the pan with the seam side down. When rounding the dough all you need to have is a smooth skin formed on the dough ball. Pizzerias tend to round their dough balls very tight to help control their spread while being fermented in the dough boxes but home pizza makers tend to use individual containers for this so rounding the dough balls tight or lose in my opinion is a moot

issue for the home pizza maker.

Note: I personally use a plastic bag to hold my dough balls so when I round the dough into balls if the dough meets three out of five descriptors of a "ball" it goes into the bag. Rounding is not critical when bagging the dough balls.

[Re: Stretch and fold versus reballing2290](#)

Thank you. I heard that they're doubling my salary for the new year! :-D

[Re: Stretch and fold versus reballing2291](#)

If you're making a thin cracker crust with 45 to not more than 50% absorption that's the way to do it (modeled after the way we make a flaky pie crust or a flaky biscuit dough), for many though a better handling dough is wanted so it's mixed JUST until it comes smooth. I'm on record as saying, "Unless you've got something going with your mixer repair man there is no good reason to mix your pizza dough beyond the JUST smooth point of development. When mixing the dough by hand any kneading beyond the point where there are no longer any lumps in the dough is purely for ones own amusement if the dough is going to receive 24-hours or more fermentation.

[Re: Stretch and fold versus reballing2292](#)

While I've not had her's it looks like a great pizza! My reference to Domino's was in reference to the crust...did that ease the ouch any? :D

[Re: Grotto Pizza - Newark Delaware2293](#)

Actually....that "marshmallowy" dough is about as far from what I'd describe any dough off of a commercial mixer as being. If it is full of "air" something is very wrong with the dough or mixer. Machine mixed doughs are smooth, but dense and moderately extensible. If you are mixing your dough to a point where it begins to take on a different appearance in the bowl (looks lighter in color) and has a smooth skin on the surface, rest easy, it has been sufficiently mixed. As for dough absorption, one of the reasons why it seems like it's all over the board is because in a way it is. Flour is quite variable, no two lots of the same flour are made from the same grist (blend of wheats used to make the flour), added to that it can absorb water or give up water from the time it's milled and if that's not enough, as flour ages it oxidizes which strengthens the gluten matrix much like the addition of potassium bromate would. Our tests have shown that flour, when stored at room temperature (70 to 80F) for a period of 1-year had oxidized to the equivalent of approximately 10-ppm (parts per million) added potassium bromate. For a bromated flour that means that the flour would perform as if it had twice the amount of bromate added by the flour miller. Like I said, flour is really pretty inconsistent.

[Re: Stretch and fold versus reballing2294](#)

Grotto Pizza from the Boardwalk is my daughter in law's favorite pizza. They live in Christiana but have a beach house just a short walk from Grotto Pizza. Good bad or indifferent, I liken it to a Domino's pizza quality wise, but then I wasn't raised on it either so my assessment of quality is HIGHLY subjective.

[Re: Grotto Pizza - Newark Delaware2295](#)

Machine mixing is WWAAYY different from hand kneading. Hand kneading is a very gentle way of developing dome of the gluten while machine mixing is a very efficient way of developing all of the gluten but the difference is with machine mixing that with machine mixing the dough tends to be tighter than with hand

kneading and with machine mixing you have the capability of over mixing the dough while with hand kneading this is a virtual impossibility. This is why I always say when machine mixing always mix the dough JUST until it begins to smooth out as this comes close to replicating the best gluten development possible with hand kneading and it also promotes a larger cell structure in the finished/baked crust. Mixing to a greater level of gluten development will promote a smaller, finer cell structure which is more bread like, this is one of the reasons why we mix bread doughs longer than pizza doughs (assuming loaf/sandwich type bread). Biochemical gluten development will provide the added gluten development necessary for gas retention during baking without adversely impacting dough handling properties or cell structure characteristics.

Re: Stretch and fold versus reballing2296

In a commercial (pizzeria) setting they mostly use dough boxes, the boxes are cross-stacked for a period of time determined by the length of time needed to cool the dough balls down to 50-55F, they are then down-stacked (top box placed at the bottom of a new stack and the stack rebuilt in reverse order with the boxes nesting for about 1/4-inch inside of each other so the box on top becomes the lid for the box beneath it, top box is then lidded. This is a very common practice. Another popular method is to use aluminum sheet pans, the dough balls are placed onto the sheet pans and the entire pan of dough balls is covered with a single plastic bag, this is placed into a rolling rack, when the rack is filled with covered pans of dough it is wheeled into the cooler for storage. This method doesn't require any kind of cross-stacking as the plastic bag offers little insulating value allowing the dough balls to cool pretty quickly and consistently. When this method is used it is common to lower the finished dough temperature into the 70 to 75F range (favoring the 70F side) while when using the stackable dough boxes 75 to 80F finished dough temperature is commonly used. If you go to my web site at <www.doughdoctor.com> you can see the dough boxes in use in Part-2 of my video series on making dough.

Another way that I like to use when making pizza at home is to place the dough balls into individual plastic bags (bread bags). After forming the dough ball, oil it and drop into a plastic bag (not a ZIPLOCK bag), twist the open end into a pony tail, and tuck it under the dough ball as you place it in the fridge. This is about as easy as it gets since you don't need to do anything more to the dough ball until you're ready to remove it from the fridge for use.

Re: Recipe for high humidity conditions....2297

You are correct, when it is stated that total dough absorption is (in this case 65%) it means that the sum of all of the water added to the dough (either as water or contained in an ingredient such as milk, eggs, or in this case a starter), when divided by the weight of the flour and multiplied by 100 = 65% (in this case). It's actually a little more complex than just that, but in this case it works just fine.

Re: Gemignani dough failure...?2298

Try to use lard that is not steam distilled (deodorized) for best flavor. The silly stuff that we have here in the States is almost all deodorized ranking it, flavor wise, right up there with Crisco. What the label shown indicates is a prepared mix....just add water and make tortillas. Included in the list of ingredients were the components for chemical leavening, and then there was our old friend L-cysteine to provide extensibility to the dough as well as emulsifiers as an anti-staling agent (did I miss something? Aren't tortillas supposed to be consumed fresh and still warm?) Oh well that the commercial market for you. The suggestion to make a

tortilla mix (everything but the water) was a good one, use that to provide the amount of tortilla mix needed for your dough. By the way, most really good tortillas are formulated with about 8% fat and about 3% chemical leavening (Calumet brand would be a good recommendation as the individual components are hard to come by outside of the commercial market) and if you do find then you will need to balance them for complete reaction using their neutralizing power to calculate the amount of soda needed) Calumet brand is a fully balanced single acting chemical leavening system as opposed to some of the others which are double acting leavening systems better suited for use in cakes and cookies.

[Re: Quaker Harina Preparada Tortilla flour](#)**2299**

While flour can have an impact I think dough absorption might have more to do with it. Doughs that are made with high absorption (above 65 to 68%) or let's just say in the 70%+ range usually perform better with more kneading done over a period of time while doughs made with a more typical absorption, say in the 50 to 65% absorption range seem to fare best when made using minimal mixing/kneading.

[Re: Stretch and fold versus reballing](#)**2300**

When I hand knead the dough (stretch and folds) I am trying to develop gluten (primarily for bread making) but when I'm making pizza I typically don't do much if any kneading as pizza doughs are typically best when under mixed with the gluten being developed biochemically during the fermentation process, when I round the dough into balls it quickly becomes so tight as to be nearly impossibly to work without ripping the dough apart, so in my humble opinion, if you are trying to develop gluten it is better to do the old stretch and fold process rather than rounding the dough as it allows you to put more work into the dough without it becoming excessively tight and bucky which makes it difficult or impossible to further develop the gluten without waiting a significant time for the dough ball to once again relax so it can again be rounded. We see this happen a lot when we re-round the dough (for whatever reason) just prior to opening it into a skin, if we don't wait long enough for the dough to fully relax it's a lot like trying to open a tennis ball into a pizza skin.

[Re: Stretch and fold versus reballing](#)**2301**

Essen1;

In the dough formulation it shows water at 64% and starter at 20%, there must be more than 1% of the total flour weight as water in that 20% starter?

[Re: Gemignani dough failure...?](#)**2302**

Lem865;

At step #5 are you placing the dough balls in a covered container or are you placing the dough balls into the fridge uncovered for at least 2-hours prior to covering/lidding? If you are doing the first, that's most likely where the problem is at, the dough balls are sweating in the containers and it's the condensation that's causing your problems, leaving the containers uncovered for at least 2-hours will allow the dough balls to cool sufficiently to prevent or minimize condensation. I would also suggest lightly wiping the top of the dough balls with a little oil after placing them into the containers as this will help to prevent any skin formation on the dough during the (cross-stacked)/ uncovered period.

[Re: Recipe for high humidity conditions....](#)**2303**

That calculates out to roughly 65% total dough absorption. Your ice water might be

slowing the rate of absorption into the flour. Have you tries letting the dough rest for 20 to 30-minutes before kneading it?

[Re: Gemignani dough failure...?2304](#)

Thank you and a Happy New Year to all!

[Re: Merry Christmas Tom!2305](#)

Even increasing the sugar by an additional 1 or 2% can help by giving more crust color which typically translates to a shorter baking time and a softer finished crust texture.

[Re: dough too crispy2306](#)

Getting your oven temperature up around 850 to 900F (or more) will help in that respect.

[Re: Wood fired pizza blisters2307](#)

It will help us to determine what the problem might be if you can share with us something about the dough prior to freezing, how you froze it and what you did with the dough after freezing.

[Re: Gummy dough2308](#)

Most non-gluten forming flours are going to max out at 25 to 30%. Be sure to follow the procedure for finding the absorption of any non-gluten flour you might add following the procedure used for finding the absorption of any whole-wheat flour or multi-grain blend. This procedure has been discussed in these pages previously in great detail.

[Re: Mystery ingredient to obtain a yellowish dough2309](#)

Your over deck is WWAAYY too cool. It might take some time for the deck to fully reach baking temperature.

[Re: Wood fired oven pizza burning on top2310](#)

For many of us 77F is about room temperature and in most cases an hour isn't long enough, more typical is at least 2-hours, some go even longer.

[Re: Wood fired pizza blisters2311](#)

Cold dough? What was the temperature of the dough ball(s) when opened into skins?

[Re: Wood fired pizza blisters2312](#)

Agreed....where is the long fermentation period?

[Re: Bianco Dough Question2313](#)

Add all of the water, then all of the flour with salt, sugar (if used) and yeast all right on top of the flour. Mix at low speed for 2-minutes if multi-speed, add the oil and mix one more minute in low speed followed by 8 to 10-minutes in second speed. If your mixer only has one speed you will be doing all of the mixing in that single speed, so just follow the same procedure, you won't be changing speeds, that's the only difference. Your mixer will mix dough sizes as small as 25% of maximum dough capacity and as large as 125% of maximum dough capacity, though I don't recommend exceeding bowl capacity as a regular practice. As soon as the dough is mixed to a smooth, satiny appearance it's done, which typically takes 8 to 10-minutes after adding the oil with the delayed oil addition mixing procedure.

Remember to adjust the water temperature to achieve your targeted finished dough temperature. I have never had to use ice water except when making frozen doughs, more typically the water temperature will be about 70F to give a finished dough temperature in the 75 to 80F range.

[Re: Basic instructions for spiral mixer?2314](#)

Cold dough and pizza ovens of any kind generally do not play well together unless the dough management procedure has been designed specifically to allow for baking a cold dough. Even refrigerated dough, if allowed to temper properly after being removed from the fridge/cooler will be in the 50 to 60F range. Doughs that are formulated for high temperature WFO baking may be too slack for many people to handle if allowed to warm much above 60F. Overall, I think it would be safe to say that there is not any direct relationship between dough temperature and baking temperature as long as the dough is within the parameters shown above.

[Re: Dough Temperature - Wood Burning Oven2315](#)

Why are you basing the amount of yeast on the water? Typically it's based on the flour weight? That being the case you're using only a little over half of the amount of yeast as you would if it were based on the flour weight. Just an observation.

[Re: Direct Dough - is it supposed to look flat?2316](#)

You should be able to buy Egg shade on line, it's not expensive at all. What's it equivalent too? I have no idea as I've never done a comparison. All I can say is that it's used in Chicago and extensively used in the baking industry.

[Re: Mystery ingredient to obtain a yellowish dough2317](#)

Absolutely! It's been in common use as far back as the 50's, and in Chicago pizzas at least to the late 1950's if not earlier. It has not effect upon taste or texture of the finished crust. If I remember correctly in Chicago they were using about 6-ounces liquid to a dough based on 50-pounds of flour weight however you will want to adjust the amount to give you the specific color you're targeting.

[Re: Mystery ingredient to obtain a yellowish dough2318](#)

Believe it or not, egg (whole or yolk) really doesn't give much yellow color to the dough or finished crust. I'm betting on Egg Shade (this is a food coloring/ Google for availability) this is the same coloring used in many Chicago pizzas which gives the crust that rich yellow color.

[Re: Mystery ingredient to obtain a yellowish dough2319](#)

Well, I am cheap as consultants go. :-D

Tom Lehmann/The Dough "DOCTOR"

[Re: Cheap dough docker2320](#)

I've used that comb on the opposite end of a hair pick with good success but never a hair brush, but if it works....why not?

[Re: Cheap dough docker2321](#)

It's a natural for that. She uses a coupe style pan that she got at WM (black on the inside and silver on the outside...go figure!) but after being seasoned and all the pizzas that she has baked in that pan it now looks more like a good cast iron skillet). She opens the dough ball as much as she can on the bench then places the dough into the greased pan and continues to work it out until it fits the pan, she lets it rest about 10-minutes and then touches it up before dressing it. She needs to

use more dough than others might use so the pizzas come out about 1/4 to 3/8-inch thick but her family loves them and she is mighty proud to be able to make them.....in the end that's all that counts.

[Re: Intro & a question](#)2322

One thing you might try is to use your favorite pizza pan (a dark colored one preferably) and use shortening, as in Crisco to lightly grease the pan, this will help you greatly to open the dough ball into a skin as the dough will act as if its glued to the pan when using shortening, just the opposite is true if you use oil, but don't worry about getting the dough to release from the pan, it'll come off just fine. I have a friend whose mother has extremely arthritic hands and this method works quite well for her.

[Re: Intro & a question](#)2323

That's a good point about Bob's Red Mill, I think they do stone grind all of their flours. I agree about those meetings, but they did keep us informed and on top of things but after 50-years, it is time for me to do MY thing and attending endless meetings is not one of them, neither is International travel, nor getting up at 6:00 a.m. and coming home at 6:00 p.m. (when I was able to come home).

[Re: Whole Wheat Flour crust](#)2324

Oops, yep, shoulda been 1-1/2-cups not 1/2-cup.

At high elevations we typically bake hotter than normal which means if you're using your home oven, pedal to the metal, give her all you can Scotty! Yeast is not normally reduced BUT you will see the dough getting larger than normal during fermentation due to the reduced atmospheric pressure.

[Re: Intro & a question](#)2325

I can't think of any stone grinding mills producing commercial flour although there might be a few local ones doing specialty flours. When you see "stone ground" on a bag it is only in reference to particle size being like that of stone ground flour. To the best of my knowledge most of the flour produced in the U.S. is made using roller mills. There are also hammer and pin mills used to make flour but these are pretty well limited to small and home type operations. I don't recall ever seeing any scientific data on how flours of different average particle size react in the human gut, that's not to say it's not out there, I just haven't seen it, and remember too that I've been retired for five years now and this is a pastime for me, no longer my occupation so I don't spend an average of three hours a day keeping up with scientific journals and attending scientific meetings.

[Re: Whole Wheat Flour crust](#)2326

In commercially milled flour you are correct in that the germ is removed but only because the oil is so unstable, it will turn rancid very fast, this is one of the reasons why white flour has a long shelf life while whole-wheat flour has a relatively short (2 to 3-weeks) shelf life. In home milling/grinding of wheat into flour sifting only removes the larger bran particles so there is still some bran remaining in the "white" flour and as you correctly state, most of the germ is still in the flour too. So there is a difference, I stand corrected. ^^^

[Re: Whole Wheat Flour crust](#)2327

The method that I mentioned is designed specifically to give the most consistent dough possible for use in a pizzeria where the dough will be held in the cooler for three days or more. When the dough is allowed to rest at room temperature prior

to scaling and balling it has had a chance to begin fermenting, to that 30-minutes add the time required to process the dough and you have the better part of an hour for the dough to ferment before it goes into the cooler. The more fermentation the dough has the less dense it becomes, things that are less dense are better insulators so it becomes more difficult to achieve consistent cooling of the dough which is a critical aspect of holding the dough for up to several days and getting consistent dough performance/pizza quality. The method used by Tony is fine for dough that will only be held for 25-hours or so, but it doesn't work well when we're looking to have consistent dough performance 3 to 4-days out. This is why all of the big box chains employ a dough management procedure very similar to that which I described.

[Re: Dough Cutting and Balling and Wrapping](#)2328

When whole-wheat flour is made the bran is separated out just as it is when making white flour, it is then reintroduced back into the flour so it constitutes 20% of the total flour weight. When you separate out the bran from whole-wheat flour you have what is affectionately known aswhite flour. Whole-wheat flour made from varieties of hard white wheat, aka whole-white wheat flour, don't have the pronounced bitterness in the bran portion due to the lack of tannins in the white wheat bran, this is also why whole white wheat flour is said to be "sweeter" than conventional whole-wheat flour made from hard red wheat varieties.

[Re: Whole Wheat Flour crust](#)2329

If you are going to be vacuum sealing the bags that'll be fine for the yeast (should be refrigerated though if not vacuum sealing). It does make a huge difference in the type of yeast used in this mix application....use ONLY instant dry yeast (IDY). As there are no other ingredients which might need refrigeration in the mix it should last at least 6-months or more when vacuum sealed but ONLY if the flour is totally free of any insect infestation. Even fresh flour can be infested but there is a way that you can ensure you won't have any insect issues for at least a year of storage at room temperature (assuming 50 to 75F) and that is to put the flour into 5# bags and freeze it for at least 30-days, this will kill both insects as well as any larvae and their eggs, once this is done the flour will remain free of insect infestation for a very long time, without doing this is's a "roll of the dice" as to whether the mix will remain free of insects over an extended storage period. While the flour millers will tell you that their flour is free of insect infestation and has a 1-year shelf life the infestation normally comes post milling during distribution or warehouse storage, we have most frequently found the source of infestation to be at the point of sale, so again, to quote Harry Calahan "Do ya feel lucky?" :)

[Re: Intro & a question](#)2330

The sifting by itself doesn't help but anything you can do to mill the bran particles into smaller pieces will help significantly. With smaller bran particles you reduce the deleterious effect upon the gluten film as well as improving the absorption rate of the bran (smaller particles = greater surface area = faster hydration).

[Re: Whole Wheat Flour crust](#)2331

What you are seeing is about par for the course. Remember, most frozen doughs are formulated with a pretty hefty dose of yeast which is why you see all the rise over the time the dough is in the fridge. Fact is, you are seeing more rise in the dough than the store does over the same period of time owing to the fact that the dough is allowed to warm more during the time it takes for you to get the dough home while the dough at the store most likely went straight from freezer to

refrigerated case where it's sold from so it was never exposed to a warming period.

[Re: could you help me reverse engineer the dough recipe from nutritional contents?2332](#)

Due to its adverse affect upon frozen shelf life I don't know of any commercial frozen dough manufacturers that makes dough with more than 30-minutes maximum time between the mixer and the freezer. PJ's doesn't freeze their dough out of their commissaries, it's just refrigerated. There are some companies making what is referred to as pre-proofed frozen, in this case they are making pre-made skins which are just slacked out and ready to use. This seems to work pretty well as opposed to freezing a dough ball since the pre-made skin is so much easier and faster to freeze than a dough ball which limits the damage of the freezing process on the dough.

[Re: could you help me reverse engineer the dough recipe from nutritional contents?2333](#)

But do remember, after the flour has had a chance to hydrate fully, you must check the viscosity and add more water if deemed necessary, then, once you don't see any appreciable change over time from the last water addition, subtract 5% from the total bakers percent of water you added and this will get you very close to where you want to be absorption wise, you may still want to make some adjustments depending upon how you're managing your dough. Also, remember that any kind of whole-wheat flour doesn't tolerate long fermentation times nearly as well as a white flour will, this is due to the cutting effect of the bran particles on the gluten structure.

[Re: Whole Wheat Flour crust2334](#)

It's really pretty easy to determine if a dough has been fermented prior to freezing, just cut the frozen dough piece in half and look at the cell structure, if the dough has a very small and uniform cell structure it has not been fermented prior to freezing. If it had a much more open, coarse/porous cell structure with a number of large holes this is good indication of at least some fermentation prior to freezing. Also, keep in mind that the order of predominance in the ingredient declaration is true only to the 2% mark, at and under 2% the ingredients no longer need to be shown in their order of predominance....so, salt, sugar and yeast could easily all fall under this rule. Many frozen dough formulas maximize the use of both salt and sugar as these are the solubles in the dough which help to control ice crystal size which contributes to the frozen shelf life of the dough.

[Re: could you help me reverse engineer the dough recipe from nutritional contents?2335](#)

Since you're talking RT fermentation the finished dough temperature is also critical when assessing how much fermentation the dough might be receiving. Assuming a 12" skin, the one that will be opened 1-hour prior to dressing and baking should be quite a bit thicker, some might say more "bread like" than the one opened immediately prior to dressing and baking. Be sure to watch the bottom bake as with that much honey you may get excessive bottom color before the pizza is fully baked at 550F on a stone.

[Re: Based on this madness.....Should I just go out for pizza?2336](#)

Whole white wheat flour (Ultragrains) is definitely the way to go. It is also available in different "grinds" so you can have a coarseness that you typically see in whole-wheat flour while still getting the flavor advantages of the white wheat. The

greatest challenge to making good whole-wheat products is in getting the dough absorption correct. I've discussed this topic and procedure a number of time in the past here if you want to research it. I've also included the topic in one of my published articles. The problem is that the bran is very slow to absorb water so if you add enough water to make a good dough by the time it's ready to use the dough is too stiff as the bran has now hydrated, to a great extent, this is where whole-wheat products have gotten a bad rap. Someone here once said whole-wheat products taste like they were made with leaves and twigs, probably a pretty apt description of products made from an under absorbed whole-wheat dough.

Ultragrain isn't as bad in this respect due to the much smaller particle size for the bran so it hydrates faster and more consistently. For the most part you will be looking at dough absorption percentages around 75% when using 100% whole-wheat flour. Products made with any amount of white flour in combination with whole-wheat flour are correctly termed as being "wheat (bread, pizza crust, etc.)" as opposed to "whole-wheat" which does not contain any white flour at all.

We used to get all of our whole white wheat flour from Farmer Direct Foods, Atchison, Kansas/800-372-4422.

[Re: Whole Wheat Flour crust2337](#)

What you are looking for is a pizza dough mix.

We can do that for you.

Do you have access to a scale or do you just work in volumetric portions (cups, teaspoons, tablespoons, coffee cans, etc.)?

I can set one up for you that will require that you portion out 3-cups of the mix and to that you will add just over 1/2-cup of cool water. I used to make this when we were deer hunting and there were four of us in deer camp, pizza was a real treat for the guys.

Here's the formula in weight measures;

Pillsbury Bread/Bread Machine Flour: 5-pound bag.

Salt: 45-grams/1.6-ounces

Sugar: 45-grams/1.6-ounces

Instant Dry Yeast (IDY): 12-grams/0.45-ounce

Place in a large bowl or bag and mix together very well. Store in a covered container in the fridge or in the freezer.

To use:

Remove 3-cups of mix and place into a bowl with a little over 1/2-cup of cool water (75F).

Using a wooden spoon, stir well to make a thick paste. Remove spoon, cover with a piece of plastic and allow to ferment for 1-hour. Oil your hands and using a plastic bowl scraper scrape the dough mass out of the bowl onto a floured surface, then knead for a few minutes, lightly oil the bowl that the dough was fermenting in, form the dough into a ball and place it into the oiled bowl, wipe the top of the dough ball with oil, cover with a piece of plastic (drape no not seal tightly). Allow the dough to ferment at room temperature for at least 4-hours, the time can be greater if desired.

Turn the dough out of the bowl onto a floured surface and begin opening the ball into a pizza skin (12 to 14-inch diameter).

Add sauce, sprinkle with herbs (garlic powder, onion powder, basil (fresh or dried) are the basics, then add the cheese and toppings, and bake on a dark colored pan in a 450 to 500F oven. Start baking on a lower rack and after about 8-minutes move it to a higher rack position to finish baking. As all ovens are different you will

need to experiment with baking.

As you get better you can experiment with placing the dough into the fridge to cold ferment for 24 to 48-hours and then see if you can find a baking steel or stone to bake on (unglazed floor tile works in a pinch) to get a crispier bake. Get ready to enjoy some great pizza and have some fun along the way.

[Re: Intro & a question](#)**2338**

I typically use 11-ounces (312-grams) for a 12" skin which gives me a dough loading of 2.76-grams of dough per square inch since a 10-inch circle has 78.5-square inches multiply 78.5 X 2.76 to get the dough weight for the 10" skin (216.66-grams).

This would be a good place to start at and then begin coming down in weight as you master the technique of opening the dough until you get the crust you're looking for.

Be aware though that fast baked pizzas are always going to have a somewhat softer, more limp crust than slower baked pizzas. They may be crispy when they first come out of the oven but just wait a minute.

[Re: Dough ball size?](#)**2339**

Please provide as much information on your dry sourdough starter as possible since some of the dry products are not active, but instead are used only to provide a sourdough flavor to the finished crust.

[Re: Cold Fermentation](#)**2340**

I second the words of "Jackitup". Around here the trip can be as much or more fun than the destination! :-D

[Re: 1984 Godfathers discontinued crust](#)**2341**

Pizzaone;

It is BUT for the most part it is fermented much differently. Whereas bread doughs are given shorter total fermentation times pizza doughs are more commonly given much longer fermentation times, almost universally the fermentation time for a pizza dough is expressed in days as opposed to hours. It is this long, controlled fermentation that accounts for the flavor and much of the textural properties of the baked pizza crust. While some like the flavor imparted by room temperature (RT) fermentation others (myself included) like the flavor imparted by cold fermentation (CF). There are good guidelines for each method that have been discussed here many times so what you might need to do is to make dough using each method and see where your specific tastes take you. NOTE: As many pizzerias work with dough made by CF this might be where you want to begin your search.

[Re: Bread flavor](#)**2342**

We have two people cutting, balling, boxing 85-pounds of dough (50# flour weight) in approximately 17-minutes with a 12-ounce scaling weight. The accepted rule is to get the entire dough cut, balled, and into the cooler within 20-minutes after mixing. After that your dough is beginning to proof and inconsistent cooling of the dough will be the end result.

[Re: Dough Cutting and Balling and Wrapping](#)**2343**

Bob;

You say you have searched for a "recipe" but can't find anything even close. Can you share with us what information you have on the formula you're searching for? Pizza doughs are pretty well all formulated within a close range of ingredients so

filling in the blank spaces shouldn't be too difficult.

[Re: 1984 Godfathers discontinued crust](#)**2344**

I can't say too much for the flavor of the dough as I seldom ever eat it, but it can sure be full of aroma. I assumed (we know how that works out) that he was referring to the finished crust when he referenced flavor (identified subjectively by taste). Is there a possibility that we are side tracked and the original question was simply "how to get more flavor in my finished crust?" and the term "bread flavor" is simply being used to describe the flavor resulting from fermentation?

Pizzaone, what say you?

[Re: Bread flavor](#)**2345**

Chris;

A couple of things come to mind when reading your post, I see that you are using "00" flour and more than 24-hours of total fermentation time. My personal experience has been that "00" flours typically do not have great tolerance to fermentation and anything in excess of 24-hours results in an unusually weak dough condition (Note: You have accurately described a weak dough in your post), so that might be something to look at. Second, your dough absorption might be a bit high so you might also want to incrementally reduce dough absorption in 2% increments to see if that helps. The acidity of your starter can have a significant impact upon dough rheology, making softer and more extensible and a reduction in dough absorption might help in that case. Lastly there is that little thing that we refer to as "technique". I open my doughs in a similar manner to what you have described, I can toss it but nothing to write home about, if you know what I mean, point is, when it comes to slapping and spinning the dough to open it I leave a lot of room for improvement so even the best dough might not work well for me if I was to open it by any other manner than what I am used to doing.

[Re: Slap/stretch dough?](#)**2346**

Just a reminder too that there is the Ohio Pizza Show put on by the Ohio Restaurant Assn. It's coming up in early January if I remember correctly. It is not nearly as big as Pizza Expo but it's still a good show to attend with a lot of low cost seminars too, and if you're on the east coast it's closer and much cheaper. Contact the Ohio Restaurant Assn for details.

[Re: Pizza Expo 2019 Registration](#)**2347**

Actually, none of them. The "bread like" aroma that you're referencing is a result of the type of fermentation the dough is given. If you want to have a bread like fermentation aroma try using 3-hours at room temperature with a finished dough temperature of 80F.

[Re: Bread flavor](#)**2348**

What you are looking to produce is a pizza similar to the bake to rise concept offered by Schwan's Foods/Tony's Pizza Service, their Freschetta Pizza is what you have basically described. I'm guessing that your concept might be a bit thinner than the Freschetta pizza. The challenges still remain the same though as the freezing process destroys the cell structure in a pre-proofed, frozen skin UNLESS the pre-proofed skin is blast frozen or better yet, cryogenically frozen. Blast freezing entails freezing at -20 to -35F in conjunction with 600 to 800 linear feet of airflow while cryogenic freezing entails freezing using a liquid cryogen (liquid nitrogen or carbon dioxide) employing a temperature of -45 to -55F in the product zone. In addition to giving you a viable skin this type of freezing is also needed to

preserve the integrity of the vegetable toppings. Similar products which you have seen on the supermarket shelves have taken this one step further by using moisture controlled vegetable toppings (this is why you seldom ever see a frozen pizza weeping water from the vegetable toppings thus turning it into a "swamp" pizza).

This is how it's done if you expect to get any realistic (21+ days) shelf life from the frozen pizza. Since I don't know what your shelf life expectations are, the best I can offer is to say "try it" but be aware that the vegetable toppings are going to suffer BADLY. This is why we harvest our gardens before they get hit by the first frost of the season, failure to do so results in everything turning into mush.

[**Re: Frozen Pizza dough**](#)**2349**

I'm on the program again this year. Looks like I'm doing two sessions with one of them a 4-hour session.

[**Re: Pizza Expo 2019 Registration**](#)**2350**

Flour: (12.8 to 14% protein content)100%

Salt: 2%

IDY: 0.25%

Water: 64%

Oil: (optional) 2%

Cold ferment for at least 48-hours before use.

[**Re: Dough Recommendations - Two Scenarios**](#)**2351**

One of the advantages of using "dough loading factor" that is often overlooked is in costing/pricing of a pizza. For example, a 12-inch pizza has roughly 113-square inches of surface area before baking. Now, ask yourself "why would anyone ever want to buy a 14-inch pizza?" The answer is because they want more pizza. How much more are they getting with a 14-inch format? They're getting about 36% more pizza. $(153.86 - 113 = 40.86 / 40.86 \text{ divided by } 113 \times 100 = 36.15\%)$. Since we can use the loading factor for dough, cheese and sauce weights we know that our cost for the same topped 14-inch pizza should be at least 36% more than that of a 12-inch pizza. If we don't use a loading factor for these critical components one may find that they are selling more 14-inch pizzas because it has more toppings or dough than the 12-inch but the pricing structure is based only on the difference in diameter...in essence, charging 36% more but using 40% more of the critical components. Do the math on \$250,000.00 in pizza sales a year and you will appreciate loading factor at the commercial/pizzeria level. At home the only value to loading factor is in determining how much of any one of the critical components we will need to use when going from one size pizza to another without changing the identity of the pizza.

[**Re: Correctly gauging TF**](#)**2352**

Assuming yeast raised donuts?

[**Re: Doughnut dough**](#)**2353**

Flour and room temperature: I wish I had a dime for each time I've heard that my dough used to perform great but not that it's winter my dough doesn't perform nearly as well....I'm not doing anything different!

During the cold winter months pizzerias get in cold flour and begin using it within 24-hours thinking it has warmed up, false...we found that it typically takes a pallet of flour several days to equilibrate in temperature and a single bag can take 48 to

72-hours. The actual room temperature can/will have a significant impact on the finished dough temperature too (while not a function of friction, it is included as a part of the friction factor correction value).

[Re: Question on GM method to adjust final dough temp](#)2354

Most pizzerias will bring out about 2-hours of dough balls and pull additional boxes during the day to maintain a usable inventory of ready to use dough balls, as things wind down a bit after the lunch trade they won't pull as many dough boxes, and if the dough balls begin getting long in the tooth they just pre-open the dough and store it on screens in a wire tree rack in the cooler, cover with a plastic bag to prevent drying then they use the pre-opened skind when they get slammed during the dinner/evening trade. Others will convert the older dough balls into bread sticks, garlic knots or something else for use later in the day.

[Re: Dough ball storage for commercial use](#)2355

Peter;

In one word: Yes, if the dough is coming out of a commissary.

[Re: Oil in 00 dough](#)2356

After the baking temperature gets much above 550F the presence of added sugar in the dough formula might begin to become problematic and if baking at 750F or above sugar can be a major issue with getting the pizza properly baked before excessive crust color development is a problem. Since ALL ovens are different my advice is to see if you like what your sugar level provides in terms of a finished pizza, if you feel the pizza needs more baking but you're limited by crust color development you most likely have too much sugar for the baking temperature being used, if the pizzas are getting well baked but you want more crust color try incrementally increasing the sugar to improve the crust color. You won't begin to detect a sweeter taste in the finished crust until you get into the 4 to 5% sugar (sucrose) level. Papa Murphy's pizza has a sweet taste in the crust and we were able to match that sweetness at 5% added sucrose.

[Re: Oven Temperatures with Sugar in Dough](#)2357

The problem with friction factor is that it is so highly variable, for example, as Tim indicated, any change in the room or flour temperature will change the FF, additionally, when mixing by machine, every mixer will have a specific FF due to differences in the way the agitator interacts with the dough, textural properties of the bowl, speed of the agitator, type/design of the mixer, as well as the amount of dough actually in the mixer. We can get away using a FF of about 30 in commercial practice since the number of variables in mixers is significantly less than it is with the home pizza maker where there is a plethora of different ways to mix the dough, from hand to machine as well as some hybrid methods too. Then add to that the fact that many home pizza makers don't even know how long they are actually mixing the dough (mixer might be running but the dough isn't being mixed as is the case a lot of times when flour is added to the bowl before the water, and then if one adds flour or water during the mixing of the dough all bets are off when it comes to mixing time. So, what to do , what to do? I think #1 has to be to focus on being CONSISTENT with the way one mixes the dough, then realize that each mixer as well as each mixing process/procedure will have its own FF for a specific dough size and formulation, with that out of the way, how to come up with a meaningful FF? I think the method developed by SAY Yeast Corporation might hold the answer for the home pizza maker, in their procedure they just use the number "145" from which the flour temperature is subtracted to give you the correct water

temperature to give a finished dough temperature in the 82 to 88F range. Personally, I think this temperature might be a bit on the high side for home use (I'd rather see 75 to 80F being targeted) so I think you will want to play with the "145", and even then I can't see one size fitting all. What I teach in my home pizza making sessions is to begin with the number 145, subtract the flour temperature and measure the finished dough temperature, if the dough is too warm use a lower number or if it is too cold use a higher number. I normally recommend adjusting the base number in increments of 5 or 10. Once you have it just write that number on the formula page for future reference, subtract the flour temperature and you should be in the ball park with regards to hitting your targeted finished dough temperature IF YOU ARE CONSISTENT IN THE WAY YOU MIX THE DOUGH.

The formula for desired water temperature that Tim was alluding to is:

3X desired dough temperature minus the sum of (flour temperature), (room temperature) and (friction factor/FF).

Friction Factor: 3X actual dough temperature minus the sum of (room temperature), (flour temperature) and (water temperature used to make the dough). Remember, in my opening comments about FF, this number will be HIGHLY SPECIFIC, and changes what so ever to the dough formula or mixing procedure can/will skew the FF number. In a commercial operation every single dough formula and dough size has its own FF.

[Re: Question on GM method to adjust final dough temp](#) **2358**

Oil can be used in just about any pizza crust dough formulation, however, do keep in mind that doughs made with very low protein flours may not tolerate as much oil as those made using a higher protein/stronger flour. Your flour blend does not appear to be excessively weak. Also, when working with high absorption doughs (68% and more) you may want to reduce the absorption by an amount equal to the amount of oil being added, this is because oil is a liquid as water is so the addition of oil to a high absorption dough can produce a softer/slacker dough than what you might want to work with. There is one more thing to consider too, that is how the oil is being added, if you are using the delayed oil addition mixing method the oil will not present a problem but if you are not it can coat some of the flour thus rendering a portion of the flour incapable of producing gluten which can have a weakening effect upon the dough as well as impact the overall dough absorption properties as the oil soaking into the flour will inhibit water absorption.

[Re: Oil in 00 dough](#) **2359**

QJ:

I don't have anything specific against single speed mixers, it's just that if I had a choice I'd always opt for the two speed. With exception to only one mixer a number of years ago I could easily live with a single speed spiral mixer, so what was the issue with the only one I didn't like? It was too fast and ejected ingredients all over the place when loaded to 50% or more of its capacity. Yes, I'd take a single speed spiral over a multi speed planetary any day of the week, unless I had a "thing" for my mixer repair man or woman, that might cause me to re-think my decision, otherwise, it's a spiral mixer for me.

[Re: Spiral mixer question](#) **2360**

QJ:

By far the easiest way to get a dough our of any mixing bowl is to put a small amount of oil (about 1-oz.) in the bowl (pour it between the dough and bowl as the mixer is running on low speed, you only want to mix like this for 10 or 15-seconds....no longer. The dough will then just about slide out on its own, makes

removing the dough really easy.

[Re: Spiral mixer question](#)**2361**

Nope, has nothing to do with mitigating the tar-taric acid if you don't soak the raisins they will hydrate during and after baking creating a dry area around each raisin and if you soak them too much they will be too fragile and be damaged during incorporation plus they will allow moisture to migrate from the overly plump raisin to the surrounding crumb where it forms a "halo" around each raisin, and worse yet, as the raisin shrinks due to loss of moisture it will fall free from the crumb when slices rather than adhering in the crumb as it should.

[Re: A bread question for Tom](#)**2362**

Wood peels without question aka prep peels (short handle wood peels) and use the metal peel for peeling the pizzas out of the oven. There is also a wood peel with a circle or circles laser etched into the peel to reference the size/diameter of the skin. These are available from <www.portionpeels.com>.

[Re: Should you use a metal peel or can you use wood to launch pizzas in woodfired ov](#)**2363**

Hey Norma! Got your ears on? Canadianpie might want to start a discussion with you, can't think of a better person. :)

[Re: side pizza business](#)**2364**

The SAF Gold is indeed designed for high sugar doughs (20++) BUT, this is a BIG BUT too, it has very little tolerance to sodium (salt). In Europe it is common to make high sugar products with not more than 1% salt, with notmal U.S. salt levels of 1.5% and above the stuff stops, dead in the water.

As for soaking the raisins, excellent idea! The best way to soak your raisins (fool proof method) is to rinse the raisins in water and then drain off all the excess water, place into a container to absorb the remaining water and you're good to go. Raisins are ALWAYS added as late in the mixing process as possible so they JUST get mixed in and not crushed or smeared. Tip: Try flavor infused raisins, add a little orange juice or even vanilla to the raisins after they have been rinsed.

[Re: A bread question for Tom](#)**2365**

You mention the need for a small refrigerator, why not get a 3-door prep-table? That should provide all the refrigeration you will need at hand.

Can you be more specific on your product mix as well as the type of pizzas you plant to make? Keep in mind that you will need to have a minimum of 1.5 times the depth of the oven as free space in front of the oven for the oven tender to safely work in. I mention this because I was involved with an operation wanting to do something very similar to what you have proposed this past summer but they didn't take into account the free space issue and that ended up nixing the deal.

[Re: Need some help, advise about a pizza kitchen](#)**2366**

QJ;

There are a couple of forces working against you here.

First, have you ever noticed that raisin bread (+50% raisins based on DOUGH WEIGHT) will not mold for a terribly long time? This is due to the tar-taric acid content of the raisins, in fact, raisin juice concentrate (RJC) is occasionally used as a "natural" mold inhibitor. The raisins are inhibiting the yeast (a member of the mold family), hence SSLLOOWW fermentation.

Secondly, with all that molasses (hopefully un-sulfured) the high sugar content

GREATLY inhibits yeast activity, adding insult to injury.

So, what to do, what to do?

Answer:

You must use a yeast spike which means changing your dough making process to that of a remixed straight dough process. After the dough has fermented in the fridge over night place it back into the mixing bowl and add 5% compressed yeast or 1.5% IDY and remix the dough just until it becomes smooth and pliable, form into balls, place on a baking surface and final proof for about 75-minutes (time will be variable), cut docking slits in the balls, spray with water and bake at 400F to 425F for about 25-minutes or until the loaf sounds hollow when tapped. Brush with melted butter immediately upon removal from the oven and drape with a towel until cool.

I also taught bread baking when I was at AIB, and for many years I was a consultant to the baking industry.

[Re: A bread question for Tom](#)2367

It all depends upon the type of wheat its made from. If it is made from a soft wheat the outcome probably won't be all that great but if it is milled from a hard wheat variety you might pull it off. The absorption will be lower than what you might be used to seeing or using and fermentation will need to be kept on the short side, I'd guess something in the 18 to 24-hour (CF) range at best, and maybe bump up the dough weight slightly too. If you're in a bind for flour ask around to see if you can find out if anyone is using one of those low protein flours to make any bread type products. The worst thing that could happen is that the miller is milling the low protein flour to a high level of starch damage, if this is the case the flour will immediately exhibit a very high (unusually high) dough absorption and it will not tolerate more than about 60 to 90-minutes of total fermentation time, after that the dough rapidly turns to soup as the enzymes in the yeast hydrolyze the damaged starch (which is responsible for carrying all that extra water) and when that happens the water is freed up and that's when the dough starts getting wet and sticky (soupy), when that happens you just toss it out and make a note to "self" not to do that again.

[Re: Is there a relation between the W and Protein %?](#)2368

Just fire out your questions and we'll do the best we can.

[Re: Roman style pizza](#)2369

Until the dough balls reach an INTERNAL temperature in the 50 to 60F range. You will need to experiment a little to determine what temperature works best for YOU (the temperature will vary with amount of cold fermentation the dough has received, your abilities at opening the dough, the dough formulation as well as ambient temperature. In a commercial pizzeria where these variables are pretty well controlled they will typically use 50F for their target temperature as to when to begin opening the dough balls, this will usually give them a period of 2 or more hours to use the dough balls, but at home where you are only making a couple/few dough balls you potentially could go above the recommended 60F upper limit but be advised that a long fermented dough or a high absorption dough might begin to get problematic in handling when opening at that temperature (like I said your ability to open the dough comes into play too, especially if you are trying to open the dough at the warmer temperatures). Yes, the dough is easier to open at the lower temperatures but if you begin opening it at too low of a temperature bubbling of the dough then becomes a problem.

[Re: How long to let dough sit at room temperature?](#)2370

Joaohess;

There is a relationship but it isn't a very good one for assessing the gluten strength characteristics of a spring or winter wheat flour. The "W" number is an indicator of the extensibility of the gluten rather than the strength of the gluten which is better measured using a Farinograph where you would be looking at such things as peak time, MTI (mixing tolerance index) and point of departure on the graph which will give a pretty good idea of the ability of the protein to make gluten as well as the strength characteristics of the gluten when formed by the mixing process. In my opinion, you are better off looking for a flour with a protein content in the 12 to 13% range.

Yes, a 15% protein content flour can demonstrate weak gluten characteristics, or it may demonstrate extremely strong, elastic/bucky characteristics which can make a pizza dough extremely difficult to deal with. When dealing with an unknown flour I always say to look at your local bakers and see what they are using, most of the time if the flour makes good bread it will also serve you well in making pizza dough.

[Re: Is there a relation between the W and Protein %?2371](#)

Peter;

When looking at the impact of salt on sweetness we found that our taste/sensory panel detected salt at lower levels than sugar and they also detected salt before they could detect the sugar/sweetness which confirms your findings. When salt is detected we tend to focus on the salt and don't perceive the presence or magnitude of sugar present, hence we don't taste or perceive the sugar as we would without the salt. We used to use the expression that it has the ability to "wipe-out" the taste buds of our sensory panel. This was important information for us to know as it would influence how we presented products to our sensory panel for evaluation since we didn't want to fall into the old adage of statisticians of "tell me what you want to show and I'll prove it statically" or in our case, tell me what outcome you want to see and I'll develop a sensory test protocol to prove it. Like Sargent Joe Friday used to say "Just the facts, nothing but the facts".

[Re: Faux sourdough?2372](#)

Wheat bran also works well too.

[Re: Best thing to use for releasing a pizza from the peel? 2373](#)

Peter;

That's it. Looks like they changed their web site since I picked up their last card at Pizza Expo.

[Re: Scale recommendation?2374](#)

For a softer, more "bread like" crust try using shortening or maybe butter/margarine/lard in the dough formula. The amount I would suggest starting at would be 5% and work up to 8% in 1% increments. As for baking, I see that you are baking your pizzas on a screen, this allows for a longer bake time but in your case you actually want to have a faster bake so I suggest baking the pizza directly on the stone/steel as JerseyPieBoy suggested, then place the baked pizza on a flat surface as soon as it comes out of the oven and I'm betting you will need to use a pie server to remove a slice. If you feel it's too soft just place it on the pizza screen to cool for a minute before slicing.

[Re: looking for soft /tender pizza bottom 2375](#)

If you are tasting salt either the salt level is wwaayy too high or you're on a salt free diet. What you are actually seeing is the development of alcohol, carbon dioxide and acids (acetic, lactic and propionic) which provide what we like to call the flavor of fermentation. This flavor increases in intensity increased fermentation. Most people like it but then there are a few who don't. Salt, while not a flavor by itself, is what many refer to as a flavor potentiator, meaning that it improves the flavor that's present while not adding a flavor of its own, much like vanilla in a chocolate cake. Formulators for convenience foods know that there are three "food groups" aka ingredients that will cause people to gravitate to a food item, these ingredients are: salt, fat and sugar. Just look at the ingredient label and nutrition fact panel on any run of the mill convenience food and you will see one or more of these ingredients standing proudly above all the rest, which is probably as good a reason to avoid these foods whenever possible. Point is, a little more salt will help to improve the flavor of your crust, regardless of how long the dough is fermented. As a product formulator for many years we found that 1.5% salt is about the minimum that can be used without impacting the flavor of the finished product and 2.5% is about the maximum that can be used before the product begins to take on certain "salty" flavor notes. I might add that in some areas where people tend to consume high levels of salt the entire salty flavor profile can be grossly distorted. If you ever sat in a restaurant and watched someone empty a salt shaker on their steak you know what I mean. We used to jokingly say that salt is addictive because when you begin using it you need more and more (actually, your taste buds just become accustomed/desensitized to it).

[Re: Faux sourdough?2376](#)

Probably the last thing you will want to add is tomato paste....just taste it and you'll know why.

If you are looking for a manufacturer of a product that might be used to thicken your sauce but yet is pure tomato (maybe some citric acid added) take a look at the Stanislaus products on their web site. Saporito Super Heavy Tomato Puree looks like it might be a good option.

[Re: Sauce from fresh tomatoes2377](#)

When using Caputo "00" flour I find that I get the best results be far using not more than 24-hours cold fermentation so there is a good possibility that your dough might be over fermented.

For a test, try this, make another dough with a finished dough temperature of 70 to 75F, test bake one dough ball after 24-hours CF and another one in 24-hour intervals to see if there is any improvement with any of the dough balls.

I have a question though "soupy" in my world this also meant wet. Are you talking about the crust being "soupy" or the center of the pizza? Excessive amount of sauce, overly thinned sauce, excessive vegetable toppings, or an excessively topped pizza baked at high temperature can all result in what I refer to as a "swamp" pizza. This is a finished pizza that is wet and "soupy" and as the water migrates into the crust it leaves a crust with little to no integrity. Can you please elaborate? Can you provide some pictures?

[Re: soupy center2378](#)

Spot-on! :)

[Re: in search of cornicione browning with GF flour2379](#)

I've never worked with that specific oven but I see that it is lined for significantly better top heat than what one typically gets in a home oven, and the oven is

designed for better/faster heat recovery than most home ovens which are "5-star energy rated", with all of that said, in the words of Big Dave Ostrander, that oven is a "stocking stuffer" when it comes to commercial pizza ovens. For the occasional home pizza baker your home oven should serve you just fine, when occasional becomes more occasional is when you might be inclined to look for something different, like a wood fired oven or bigger like a great deal on a used commercial pizza oven that you can install out in the garage.

[Re: Baker's Pride oven?](#)**2380**

That's 2% (bakers percent) i.e. 2% of the flour weight.

Decking a pizza is starting it out on a screen or pan and then removing it from said screen or pan and placing the pizza onto the deck to finish baking. It is also used to re-freshen pizza slices that have been held in a holding cabinet until time of sale.

[Re: in search of cornicone browning with GF flour](#)**2381**

2% sugar will not change the taste at all. If you use a screen it would be used just as you are presently baking. Placing the skin on a screen will allow for a slightly longer baking time (maybe sufficient to get some top color) then when you remove it from the screen and "deck" the pizza you will get the bottom crust color development. You just need to figure out how long to bake the pizza on the screen before decking it. I also suggest trying a higher rack position to get a compromise of top and bottom crust color. The addition of some sugar to the dough formulation will certainly help in achieving a better crust color as you move the bake to a higher rack position.

[Re: in search of cornicone browning with GF flour](#)**2382**

Try putting 2% sugar in the dough formula. Bake one on the deck as you have been and the other one start out baking on a screen for about 1/2 of the bake time then remove from the screen and finish baking on the deck.

Assuming you're baking in an upper rack position to provide the most top heat?

[Re: in search of cornicone browning with GF flour](#)**2383**

I don't remember the exact percentages anymore but brewers yeast will ferment up to about 13% alcohol content and bakers yeast will ferment up to about 1% less than that, still well under the alcohol content of beer as we know it, and don't forget that it will also be further diluted by the water that you're adding to the dough so there is really nothing to worry about. Beer is also slightly acidic, yeast likes an acidic environment (within reason) so the two play quite well together...don't believe everything you read on the internet. :).

[Re: Faux sourdough?](#)**2384**

With a flour protein content that low (10.3% +/-) I suggest targeting a finished dough temperature of 70 to 75F (not more than 75F), and then following as closely as possible the Dough Management Procedure which I provided to you. The dough should be ready to use after 24-hours cold fermentation with a maximum life of 48-hours. After the cold fermentation process, remove the desired number of dough boxes from the cooler, leaving them covered, allow the dough to temper AT room temperature until the internal temperature of the dough balls is in the 50 to 55F range, at that point you can begin opening the dough into skins for your pizzas, the dough balls will remain good to use at room temperature (just be sure to keep the boxes covered) for another 2 to 2.5-hours. Cold dough at the time of opening doesn't cause the dough or finished crust to absorb moisture but it can have a dramatic impact upon how well the pizza gets baked and I think this is what you

are seeing as when the dough doesn't get properly baked in the center the finished crust quickly turns soft and soggy which could be mistaken for absorbing moisture. Since so much of your business is DELCO I would advise using a longer, slower bake, something around 6-minutes at about 525 to 550F as this will provide for a drier pizza with a crispier bottom crust which will hold up to the abuse of DELCO better than a fast baked pizza.

[Re: New to Pizzeria business questions 2385](#)

Total fermentation is typically calculated at 2% which includes loss due to fermentation as well as moisture loss, so $0.98 \times$ actual dough weight (after mixing) is what is used to calculate the dough weight after fermentation.

[Re: Bread starter scaling up wierdness?2386](#)

I tens to agree with you. Beer is really nothing more than a preferment, much like a starter. One question I have is why did you go to the effort to separate the beer from the other ingredients by adding it late as you did? When I've used beer I just add it right into the water, also we found that a darker/stronger beer provided a better flavor than lighter colored beers.

[Re: Faux sourdough?2387](#)

That's a really tough question to answer as it boils down to taste and that's such a subjective assessment. From a text book assessment a product made from a dough with less fermentation will have a more bland, less complex flavor while a product made from a dough made with more fermentation will have a stronger, more complex flavor generally accompanied by a slight to moderate tartness on the tongue. From a mastication stand point the product made with less fermentation will typically have a tougher, more chewy eating characteristic than one made with more fermentation. To some extent I also use crust color, or lack of to assess fermentation, as the dough ferments sugars are converted to carbon dioxide, alcohol and acids (which inhibit crust color development) so a product with a lighter crust color MIGHT have been made from a dough with more fermentation. If I am trying to ascertain the amount of fermentation that might have been used to develop a specific product I begin putting all of these markers together (visual, textural/mastication, flavor and overall appearance) to gain some perspective of how much fermentation might have been used to develop a specific product. In bread items I would include aroma which by itself can be a pretty good indicator but in pizza crusts it is all but impossible to make an effective aroma determination.

[Re: VPN recipe - baker's yeast2388](#)

They work quite well, and with a good one you can expect to see a baking time of around 7-minutes. For the money, the Marsal deck oven is a good one.

[Re: pizza oven for new york style pizza2389](#)

There is a sweet spot in fermentation beginning where the dough can first be successfully used until it is over fermented to the extent that it no longer makes an acceptable pizza or handling of the dough becomes too problematic. At that low of a CY level and 3% salt the dough is fermenting very slowly and is still within the parameters of that sweet spot. This doesn't mean that the fermentation is the same, it just means that it hasn't yet progressed to the point where it becomes problematic. We even see this in doughs that are used in a commercial operation, take for example my typical dough formula with 0.375% IDY and 1.75% salt using my CF dough management procedure, with a finished dough temperature in the 70

to 75F range the dough is ready to use after 24-hours with a useful life of up to 72-hours or a little more. This simply means that the dough will make decent pizzas (within some range of quality standard) that the average consumer can't differentiate (consistency is the name of the game) over the life of the dough, yes, there is a difference in fermentation but not so great so as to negatively influence the handling properties of the dough or diminish from the expected quality standards of the finished crust/pizza.

[Re: VPN recipe - baker's yeast](#) **2390**

I'm on the same boat, I use what is available to me locally and as many of you know, I use fresh whenever possible. Fresh basil right out of our garden, vine ripened tomatoes sliced and used instead of a sauce, toppings right out of the garden and occasionally I'll use some locally harvested organic venison. Our garden is finished for the year now so I'm really going to miss it until next spring :(One of the questions I used to ask my students was to define quality in one word. The answer was "perception". It ain't the ingredients that count, it's what you do with them that makes the difference.

[Re: Why Is It So Hard To Get Great Ingredients?](#) **2391**

If the dough is too elastic from the "get-go" when opening the dough ball into a skin the problem is most likely due to insufficient fermentation for the strength of flour being used. The second reason, especially in pizza making where long fermentation times are typically employed is over fermentation of the dough. In this case the gluten is tight (aka bucky) and just doesn't want to stretch at all and all attempts to open the dough just result in tearing. In the case of an under fermented dough you will be able to open the dough without tearing but it will just keep pulling back to a smaller size/diameter.

[Re: What are the main causes \(probably\) when dough keeps shrinking when spreading ?](#) **2392**

I'll give you an AMEN to that! :).

I'm now enjoying retirement more than I ever thought I would.

[Re: Dozens of New England Papa Gino's locations abruptly shut down!](#) **2393**

That's how some of the "pocket sandwiches" (don't want to use the trade marked names) are made. They're then frozen and finished in the home oven from the frozen state. The frying process gives it a whole different flavor.

[Re: Deep-fried Calzones](#) **2394**

Momba;

I can answer all of your questions but first I need more information.

What type of pizza are you making?

Tell me as much as you can about your flour.

What about your business concept? Dine-in with some DELCO or primarily DELCO? If you will email me at <thedoughdoctor@hotmail.com> I will be glad to send you a copy of my Dough Management Procedure, this may come in handy for you as I'll be referencing it in my response.

[Re: New to Pizzeria business questions](#) **2395**

Sure, not a problem if you have the overhead space for the hood and you will also need to have some steps built so the oven tender can reach the top deck. I will add this, having them stacked 3 high makes an even bigger pain out of a painful job.

[Re: Stacking deck ovens](#) **2396**

Try putting all of the water in, then add the salt and sugar(if used) to the water, add the flour and the yeast on top of the flour, use the delayed oil mixing procedure, see if that works any better....it might help a bit but I think your problem might be with your dough hook being a common "J" hook rather than the much improved reverse spiral dough arm which was designed back in the early 1970's to address this very problem. That might be the good news, the bad news could be that there is no reverse spiral dough arm made for your mixer, do an internet search as well as contact the Hobart Corporation in Troy, Ohio (USA) to see if they have any or if there is any compatibility with another size Hobart Planetary mixer (this would be a very long shot).

If you can send us a picture of your dough hook I'm sure we can identify it for you pretty easily.

One last thing, the problem with the dough climbing up on the hook is usually at its worst when mixing smaller dough sizes and very large dough sizes (based on bowl capacity). Mixing intermediate size doughs and using a higher mixing speed can help in many cases.

[Re: Hobart Tallboy Dough Riding Up](#) **2397**

It all has to do with the finished volume/height.

Bread is expanded much more than pizza dough immediately prior to baking (proofing).

The oven spring is typically, but not always greater for bread doughs than for pizza doughs.

Due to the much greater expansion (16-ounces of dough can be expanded to nearly 2700 cc in volume (baked loaf volume), the dough needs to be significantly stronger than a pizza dough which will be expanded to a height of about 1-inch for pan style crusts or 0.25-inch or less for thin crust styles.

Some bread doughs receive very long fermentation times just like pizza doughs and some receive less than 5-hours fermentation time, like some pizza doughs so fermentation for both is all over the place, but one common characteristic to most pizza crusts is an open, porous crumb structure while indeed some breads also have this characteristic other bread types (sandwich breads for example) are targeted to have a very dense, tight knit crumb structure which few pizza types are targeted for. One of the ways these characteristics is achieved is through manipulation of the dough mixing time which is typically shorter for pizza dough and longer (more gluten development) for bread dough.

Why is it that bakers don't really know how to make good pizza? The answer is in the fact that most bakeries don't sell pizza and add to that their ovens are not really designed for baking pizzas either. It goes the other way too, I have dealt with many pizzerias wanting to make different types of breads, especially hoagie buns, these items just have not historically been on their radar screens.

I'm sure there are a bunch more but it's approaching "lights-out" time so I'm going to quit while I'm ahead.

[Re: "Pizza is not bread": I want to know why!](#) **2398**

Absolutely! In addition to actually killing any insects and their eggs freezing the flour will ensure a more consistent performing flour over extended periods of time. Just remember to remove whatever amount of flour from the freezer the day prior to baking to allow it to completely warm-up. One thing that many of us do is to pre-portion the flour into individual plastic bags prior to freezing, this way all you need to do is to remove a single bag the day/evening before you want to use it and you're good to go on the following day or if your plans get interrupted it can sit out in the

closed bag for 2 or 3-weeks.

[Re: Can I keep my pizza flour in the freezer?2399](#)

Great information, thanks for sharing! :)

[Re: Lloyd Pans vs. Allied pans, and Bar Keepers Friend...2400](#)

In a convection oven the use of a dark colored sheet pan would also help the bake. While they are available, I think it's easier to just season the OUTSIDE of the aluminum sheet pans which are going to be used for this specific application. I also agree that the use of stones on the bottom of the oven would help as well.

[Re: Commercial convection oven2401](#)

Well....that being the case, I hear they have a number of opening for airline pilots. All you need is a pilot's license and you can go thundering through the skies at 500 m.p.h. with 200 people sitting behind you cheering you on!

I wish you luck in the pizza business.

[Re: Opening a shop with zero experience 2402](#)

When I first started in the baking industry, back in the early 60's it was common for the sponge mixer to have a bucket of warm water next to his mixer, he used to take a small piece of each sponge just as it was finished mixing, roughly ball it (about the size of a hen's egg) and drop it into the warm water, it would initially sink as it was denser than water but in a few minutes, as the yeast began fermenting it would float, providing an indication that the yeast was indeed added to the sponge and that the sponge was active. That's all the test is good for, nothing more, nothing less, anybody who tries to read more into this simple test would also float in a bucket of warm water as they're full of hot air! Proving once again that everything you read on the Internet.....

[Re: Dough floating when done fermenting?2403](#)

Any type of oil, not just olive oil helps with the doughs extensibility, shortening seems to help deep-dish pizzas rise better than oil which we confirmed in bread making tests back in the 1970's when the wholesale bread industry converted from shortening/lard to vegetable oil.

As for adding shortening.....go back and re-read my previous response beginning with "Here's a simple test", and the answer will be right there.

Give your brain a rest, you're over thinking this and maybe trying to absorb too many things at once, lean back, take a deep breath, and get back to making pizzas for fun again! :)

Don't be afraid to experiment, but remember to change just one thing at a time, always weigh your ingredients, and keep notes on what you did. Remember, when it comes to pizza, even our mistakes can taste pretty good. Did you know that the Schlotzsky's bun is the result of a mistake? Ditto for the bagel and pretzel too.

[Re: Looking for a little more flavor in my dough?2404](#)

This seems to be a common experience with the Lloyd pans and Detroit style pizzas. While the Lloyds Pans are great with other types of pizzas there seems to be an issue only with the Detroit style pizzas. This has been discussed here previously and there were recommendations to use the old, original type, blued steel pans which never showed this problem. If I remember correctly, there was a reference to a supplier of these pans in one or more of the posts. Maybe Peter can work his magic for us by locating those conversations.

[Re: Lloyd Pans vs. Allied pans, and Bar Keepers Friend...2405](#)

I do an "either or" with oil and shortening but you could blend them if you had a specific purpose in mind. Since shortening is 100% fat oil and shortening are used at the same levels unless you are using something which contributes a flavor and you want to accentuate that flavor in which case you would use more. Ditto for the oil too. Butter and margarine are not shortenings as they contain 20% water so if you were to use either of these at the same level as the oil you are presently using you would be decreasing the amount of oil being added by 1/5th (20%). Here's a simple test to determine if any fat can be added directly to the dough or if it should be added by the delayed fat addition method. Place a small amount of flour on a plate, add some of the fat in question to the flour (just put it right on top of it), if the fat begins soaking into the flour it should be added by the delayed fat addition mixing method but if it just sits there doing nothing more than looking pretty you can safely add it to the dough along with the rest of the ingredients. Note: Lard can be a toss-up as to how it is added depending upon the temperature of the lard at the time of addition. If it's warm you will be better off adding it by the delayed method but if it's cold you can add it just as you would add something like Crisco. To some extent the same might be said for butter too, there are significant differences in butter when it comes to slip point (melting point). Typical American butters have a very narrow plastic range while imported Danish butters have a much wider plastic range (butter with a wide plastic range can still be relatively soft right out of the fridge and doesn't melt at elevated room temperatures). This is the type of butter from which Danish pastries were originally made. Today, at least in the U.S. we use a specially formulated fat (roll-in shortening) for making Danish pastries which has the desired plasticity range necessary for the rolling/layering process (laminating) used in making this type of pastry.

[Re: Looking for a little more flavor in my dough?2406](#)

AND/A&D Weighing makes some almost bullet proof scales. One year at Pizza Expo they were dropping one off of the table onto a carpeted cement floor without any damage to the scale. We had them for our students to use when I was at AIB too. Best part is that they operate off of inexpensive flashlight batteries, which by the way, seem to last forever. <www.andweighing.com>

[Re: Scale recommendation?2407](#)

From a function standpoint lard is just like any other regular plastic fat, but it does have a flavor. Essentially all lard sold in the U.S. is steam distilled (deodorized) to remove this flavor component but if you can get some pure, non-steam distilled non-deodorized), lard it will contribute a unique flavor to the finished crust.

[Re: Looking for a little more flavor in my dough?2408](#)

I've stacked them in two high, more than that high and you get the sandwiched dough ball effect where you don;t get consistent cooling of the center dough balls....otherwise, packem' in. Just remember to oil the dough balls when placing them into the bags and use bread bags if you can or a similar "food" bag like you get on a roll at the supermarket.

[Re: Storing lots of pizza doughs2409](#)

In all my years I've never seen a case where the specific topping had any influence on the bottom crust color characteristics unless as previously stated too much was used or a "swamp" pizza was in the making. In cases where a VERY thin skin is dressed the heat from the deck will just pass right on through the crust, as it is not thick enough to create a thermal break, and go into the toppings, but that is not a

function of the toppings, instead it is a fault of the skin being made too thin. Every oven is a law unto itself and only itself.

[Re: sourdough - hydration and toppings2410](#)

If you're not checking the stone temperature or allowing sufficient time for the stone to recover heat anything is possible.

[Re: sourdough - hydration and toppings2411](#)

First off, the mechanics of oil v/s shortening; The shortening does a better job of coating the gas cells within the dough which allows them to better retain leavening gas, expanding air and water vapor which results in improved (greater) oven spring which in turn typically results in a crispier crust, oil, on the other hand, is just absorbed into the dough to act as a lubricant and while this can enhance oven spring the effect generally isn't as effective as the shortening due to its combined gas retention properties.

Now, if you are looking for some impact upon flavor, have you tried using a Pomace grade olive oil? It has a much more robust flavor and is my own personal "go to" oil to use in my pizza doughs. As for other types of fat such as butter, butter flavored margarine, butter flavored Crisco, butter oil, Butter Buds, etc. if that's the flavor profile you're looking for in the finished crust....go for it. Experiment with them at different levels to determine where your preference lies.

While some reduce water when adding oil to the dough formulation, I have never found it necessary to do so unless I'm already pushing the limits with my dough absorption. Just remember to use the delayed oil addition mixing method when using an oil, this is not necessary when using a plastic fat.

[Re: Looking for a little more flavor in my dough?2412](#)

If the dough is showing sufficient oven spring it shouldn't make a lot of difference as to the kind or amount of toppings used, if too much is used it will weigh down the dough thus limiting oven spring which makes the dough more dense and better capable of conducting heat through it which will reduce the heat to the bottom of the pizza making for a lighter finished crust color. Lots of veggie toppings put off a lot of moisture during baking which shrouds the top of the pizza in cooler moist air resulting in a lighter overall top color, this is why a lot of times we see a meat only topped pizza having a darker top color as there isn't as much cooling moisture covering the top of the pizza during baking. Mind you, this applies to deck ovens only, the high velocity airflow of an air impingement oven pretty well eliminates this issue.

[Re: sourdough - hydration and toppings2413](#)

Are you asking if the toppings (type /amount) would impact the bottom crust color?

[Re: sourdough - hydration and toppings2414](#)

Your pan seasoning looks great. It'll continue to darken with continued use (that's a good thing), but do NOT wash your seasoned pans, just wipe them out with a clean, dry towel and they'll be good to go the next time pizza is on the menu.

[Re: UK: pizza pans and chopping board2415](#)

The amount of malt added by the flour mill is variable and adjusted to provide a targeted Falling Number (recently discussed in another post) so I wouldn't recommend adding malt at a fixed amount, if you do want to go that route I'd suggest adding 0.25% of a 20-L malt powder. Instead, it might be easier for you to just include some sugar in your dough formulation. You should be able to bench

mark the sugar at 1% and work up or down from there. Once you have the amount of sugar dialed in it can probably be considered a constant UNTIL you change your grist (wheat being ground into flour), then if you see a change in crust color you will need to adjust the sugar level accordingly.

[Re: how much malt to add to home ground flours](#)**2416**

I would suggest experimenting with the total dough absorption as that is almost universally the number one variable in dough formulation. Adjust the absorption in 2% increments up and down until you find the absorption that works best for YOU under YOUR specific conditions and Your dough management procedure. As for the cream cheese, it's probably the high moisture content of the cream cheese (55%) and/or the acidity of the cheese that is preventing the cheese from browning during baking, cream cheese is pretty low in fat content at only about 33%.

[Re: sourdough - hydration and toppings](#)**2417**

I'm humbled by your comments. My training Through the AIB has been as both a researcher and an educator where we used education and assistance as a means of disseminating new found knowledge. One of my idioms is "Knowledge gained and not shared is knowledge lost". There is a lot of shared knowledge here as well as at the PMQ Think Tank and I'm pleased to be able to contribute to just a small part of it.

[Re: restaurant consulting](#)**2418**

Nick;

I'll be glad to work with you BUT there are a lot of things that you need to do on your part before moving ahead.

Please feel free to contact me directly at <thedoughdoctor@hotmail.com>.

[Re: Pizza Consultant - SE Michigan](#)**2419**

I have been a consultant to both the pizza and baking industries since 1968 and since my retirement from the AIB five years ago I have been charging \$1,000.00 per day for my consulting services (a LOT less than what they were when I was employed by the AIB), if the job is a small one, requiring less than a day on my part I charge \$125.00 per hour.

[Re: restaurant consulting](#)**2420**

If I remember correctly I think we might have something here on the function of the various ingredients used in making pizza dough, aside from that, sugar is multi-functional in yeast leavened dough, at low levels (typically 3% and less) it provides a nutrient for the yeast to feed upon during long fermentation times and it can also precipitate crust color development or enhance crust color. At higher levels it can have an influence on the flavor of the finished crust by providing a sweet taste or even a unique taste/flavor depending upon the type of sugar being used. For example, non-diastatic malt can add a nutty or even a malted milk type flavor to the finished crust while lactose provides essentially no sweetness but instead has a significant impact upon crust color characteristics, honey, can provide a broad spectrum of flavor to the finished crust depending upon the color of the honey. The lighter shades of honey provide less flavor while the darker shades provide more flavor but the color of the honey doesn't impact the crust color characteristics. Un-sulfured molasses will provide yeast nutrient to sustain yeast activity while also contributing to crust color and providing a unique flavor to the finished crust. The type of pizza being made can also dictate the use of sugar in the dough formulation however, in many cases when sugar is not used, an un-malted flour is used which

means that you will need to be baking your pizzas at high temperatures (above 750F) if crust color is to be achieved, if your oven is not capable of baking at this temperature you might find yourself needing to add a small amount of "sugar" to precipitate the browning reaction allowing you to get a decent crust color on your pizzas.

[Re: Sugar in dough](#)**2421**

What kind of temperatures are we talking about?

[Re: steps after a 24 hr cold proof](#)**2422**

Hey man...I understand fully! When I'm posting late at night I have trouble spelling my own name correctly! ^^^ :-D

[Re: Opening a shop with zero experience](#)**2423**

You will not want to apply heat to the dough in any way unless it is humidified heat. If you heat the air it won't appreciably speed the warming process but since warm air holds more moisture than cold air it will have a significant drying effect upon the dough resulting in the development of a crusty skin on the dough ball(s). Leaving it warm AT room temperature normally takes about 90 to 120-minutes. This is a good time to be pre-heating the oven and prepping the toppings.

[Re: steps after a 24 hr cold proof](#)**2424**

What was the baking temperature in their wood fired oven as compared to your oven? Aside from temperature, all ovens bake differently for a myriad of reasons, someone one said "Every oven is a law unto itself and only unto itself". I'm guessing you're just going to need to experiment with baking pizzas made using that dough formulation and that dough management procedure to find the baking conditions needed to give you the pizza you're looking for.

[Re: Wood vs propane results](#)**2425**

Doesn't that hurt? Building an oven on your fingers. :-D

[Re: Opening a shop with zero experience](#)**2426**

Both wood and gas produce moisture/water as a by-product of combustion. Were the baking conditions the same? How about the way the dough was managed or handled prior to baking? Too many variables here to be definitive.

[Re: Wood vs propane results](#)**2427**

When it comes to electric ovens I really like the Sveba Dahlen brand ovens out of Sweden. Lately they've had a booth at Pizza Expo.

[Re: Gas Oven](#)**2428**

I don't know what their temperature rating is but we never had any issues with them charring at our baking temperature of 500F. Crispy yes, but not so that it would break off in the oven or even when removed from the oven but when we tossed them into the trash you could feel that they were definitely crispy. The part that is covered by the pizza won't get up to anything even close to 500F, and I doubt that the part of the paper sticking out around the edge of the pizza gets much above 400F due to the cooling effect of the pizza during baking.

[Re: best pan/surface for gluten free crust](#)**2429**

When we made them at AIB we used to bake them on the silicone baking sheets (not the mats), right on the deck. The heavier weight ones work better than the

flimsy, light weight ones.

[Re: best pan/surface for gluten free crust](#) **2430**

It's a lot easier to control amylase than damaged starch. The malt by itself will help to create crust color.

[Re: Falling number... Amylase activity or damaged starch ?](#) **2431**

It could be that you're using too much salt, try making a dough with 1/2 of the amount you're presently using, that will get you pretty close to a typical level of 2%, if that helps you can always incrementally work up to suit your taste.

[Re: Dense/ doughy crust](#) **2432**

You might also place your post in the Think Tank at <www.pmq.com>. That site is visited mostly by owners/operators and they might be able to provide you with some additional first hand input.

[Re: High Temp Gas Ovens](#) **2433**

Your option #1 could be very viable if done right. I'd suggest striking up a conversation with Norma as she is just now getting out of operating a successful operation like that and I'm sure she could provide some valuable advice as to how to get started.

Good Luck,

[Re: Local Pizzeria Closed.. Desperately need help to move fast w/my new Startup!](#) **2434**

Amylase activity. Falling Number does not measure damaged starch. The fact that the FN is high is the reason why pizzas made using these flours must be baked at very high temperatures, UNLESS amylase or sugar is added to the dough formulation, then it performs more like any other normally malted flour.

[Re: Falling number... Amylase activity or damaged starch ?](#) **2435**

As a note to this story, I have been personally involved in the development of two different pizzeria operations (as a consultant), both of which were valued at over \$1,000,000.00 (ground-up construction), both were essentially built for "the kids", once completed and opened it we found that the "kids" enjoyed hanging out at the pizzeria with their friends but work of any kind was simply off of their radar screens and both failed within a year and since "Daddy" had no previous knowledge of the pizza industry attempts to find someone to operate the business also failed. Both operations had totally failed within two years of opening, hence my first post to this thread. My good friend Adam Peyton, owner of AJ's New York Pizzeria here in Manhattan, Kansas bought the ovens from one of those failed businesses for pennies on the dollar.

[Re: Opening a shop with zero experience](#) **2436**

Stone mills do not damage much starch at all, to do so the stones would essentially need to contact each other and we know this doesn't happen. This is also why stone ground flour is coarser than roller milled flour, in fact the most coarse type of whole wheat flour is known as "stone ground" even though it's milled on a roller mill.

[Re: Falling number... Amylase activity or damaged starch ?](#) **2437**

The typical U.S. roller milling process results in flour with about 6 to 8% damaged starch which is about all that you can get with a roller mill. To achieve a higher

level of damaged starch ball milling or pin milling is required. In Mexico they do as high as 20% damaged starch in some areas (the reason for this is because local bakers thing the ability to get more water into the dough makes their products cheaper to make due to the higher yield BUT the truth is you have to bake out all of that extra water. Finished bread will have a maximum moisture content of about 40 to 42%, higher than that and the finished bread is doughy. Hamburger/hot dog buns come in at around 36% moisture and pizza crusts come in at around 26%, crackers come in at about 6 to 8% BUT they can achieve that moisture content ONLY by passing the crackers through what they refer to as a "kilning" process which is a process where the crackers are passed under the baking chamber at a slow speed to drive off additional moisture, they're then packaged HOT as they will pull moisture from the air at that moisture content. I digress.

Back to Mexico, to get the amount of starch damage they're looking for they pass the flour through an Entialtor several times which is nothing more than a pin mill which is designed to break up insect eggs in the flour but when the flour is passed through it several times it becomes a pin mill which results in significant starch damage. When we studied starch damage at AIB we found that pin milling was the most effective and fastest way to damage the starch.

[Re: Falling number... Amylase activity or damaged starch ?2438](#)

Sorry to say this but this sounds like the prologue to a horror story.

[Re: Opening a shop with zero experience 2439](#)

Stuart:

It looks like all of your water is "warm water". The only portion that should be warm is that which is used to activate the ADY in (100 to 105F) with the remainder being cool water (typically about 70F). The salt level is low at only 1% 10-grams per Kg. flour), for both flavor and controlling the rate of fermentation the salt level should be between 1.75 and 2.5%, or about twice of what you are presently using. Form your description it sounds like the dough is being over fermented and 14-grams of ADY per Kg. flour isn't helping the cause. For your dough management procedure I think you'll be better served using only 2 to 3-grams of ADY.

[Re: My dough isn't stretchy and elastic Im doing something wrong. 2440](#)

The issue with damaged starch and amylase activity, as has been explained previously, is that damaged starch has a very high absorption as compared to non-damaged/intact starch. In effect, the damaged starch is responsible for and mostly carrying the increase in dough absorption...now we add amylase into the equation, the amylase hydrolyzes the damaged starch into dextrins and/or maltose and the water that the starch was carrying is now freed up to act as non-bound water in the dough making it overly soft and sticky. Some flours can have a naturally high amylase activity (especially those which were made from wheat which had been allowed to sprout prior to or after harvest), these wheats are typically considered as having little or no application in the baking industry and end up going into channels destined for the industrial wheat market for use in such things as adhesives, and well drilling paste. This is why it is important to know and control the amylase activity of any given flour.....a little is good for fermentation and crust color but too much can/will make a mess of things.

It must also be remembered that flour with a high level of damaged starch (15% and above) will have similar issues even without added amylase as there are enzymes present in the yeast which readily attack and hydrolyze the damaged starch, again creating a wet, sticky dough situation during the fermentation process. This is one reason why in countries where the flour is milled to high levels

of starch damage the dough fermentation times are held to not more than an hour. I neglected to take this into account when I was in Guyana and after a 3-hour room temperature fermentation period we had to "pour" the "dough" out of the bowl....Oops!

[Re: Falling number... Amylase activity or damaged starch ?2441](#)

Nope, not unless it's inverted. You can put sucrose into a pan and heat it until it melts to a clear liquid and it won't develop any color. This is the reason why angel food cakes are made using only sucrose (sucrose is the sweetest of the common sugars and it doesn't provide any color) The little bit of crust color seen on an angel food cake is due to the Maillard browning reaction with the egg protein. The enzyme invertase inverts the sucrose into reducing sugars (dextrose and fructose) almost instantly which are responsible for the impact on crust color which we see when including sucrose in a yeast leavened dough formula.

[Re: 5 Minute Thin Crust Dough2442](#)

Are you sure you can tackle this by yourself? Let's see....you will be prepping pizzas, tending the oven (out back), cutting, boxing or bagging, and running the front counter as well as table service (if you have it)? You're going to go broke at the cost of the gloves you'll be buying. Maybe I'm missing something but I just can't see this as a one man show. Just trying to be realistic not discouraging. Scaling up your dough to a 30-qt. mixer is easy. If you have a Hobart HL-30 mixer the capacity is about 18-Kg of total dough weight at a minimum of 60% absorption or half of that at 50% dough absorption. If your mixer is old/tired it may not work well at full capacity so let's fudge a little and use dough weights of 15 Kg. and 7.5-Kg. At 15-Kg. you have 33-pounds of dough weight. Add up all of the bakers percent for your dough formula, divide this by 100 then divide the new dough weight (33-pounds) by that number. This will give you the flour weight needed to make your new dough weighing a total of 33-pounds. The rest is easy, just bakers% X flour weight (press the "%" key) and read the ingredient weight in the display window.

[Re: Local Pizzeria Closed.. Desperately need help to move fast w/my new Startup!2443](#)

Actually, adding sucrose (cane or beet sugar aka table sugar) won't help the crust develop any color. This is because sucrose is not a reducing sugar, it depends upon the enzymes in the yeast to reduce it to sugars capable of providing crust color, so you will either need to include a small amount of yeast or use corn syrup or dextrose solids to improve the crust color....then too you could always figure out how to bake it at temperatures of 800F or more in which case sugar would be a moot issue.

[Re: 5 Minute Thin Crust Dough2444](#)

What you saw when using colder water was perfectly normal. When making slight adjustments in the dough temperature (assuming "normal" temperature in the 75 to 85F range) we normally figure that a 5F drop in water temperature gives us a 2F drop in dough temperature. The reason for this is because all of those ingredients are really nothing more than a heat sink.

It sounds like you were putting a lot of oil onto the dough balls. The correct amount is JUST enough to see a shine on the dough ball. Since oil is a tenderizer in the world of ingredient function it will contribute to a softer eating finished crust if used in excess. I never use oil on the bottom of the dough ball as it results in the dough balls skating around in the dough box....not a good thing. The only time I

ever oil the entire dough ball is when I use a plastic bag to ferment the dough ball(s) in, which anymore is most of the time come to think of it.

Putting flour on the bottom of the tray.....moisture migrates from the dough ball into the flour, thus hydrating it, and turning it into school paste over time which is not conducive to east removal of the dough ball. Try plastic bag fermentation, once you get the hang of it you may like it, I use it as do others here and it works well. Look Ma! It just falls out of the bag by itself!! :)

[Re: Olive Oil and Dough Balls and Finished Dough Temperature](#)**2445**

Where are you planning to have the small wood fired oven? What are you going to do for a refrigerated prep table? How many employees? Are they already set up for self-serve soft drinks. To me it sounds like at least a 3-person operation which is going to be tough for such a low income area, but if you have enough seating your draw from the surrounding area can have a positive impact if you play your cards right. In all probability you won't have a beer/wine license so that'll hurt average ticket cost. You can off set some of this by looking for a really good dessert, either locally made or frozen and shipped to you (cheese cake?).

If you want to discuss please feel free to contact me at 785-537-1037 (please email me at <thedoughdoctor@hotmail.com> with a date and time to make sure I'll be here to take your call. We're on central time right now.

[Re: Local Pizzeria Closed.. Desperately need help to move fast w/my new Startup!](#)**2446**

Small place, small town, only open until 1:00 p.m.....Am I missing something? It seems as if you are locked into a very short lunch trade with an initial maximum of only 30-pizzas at most. What are the local demographics? Small town but a lot of people work there?

[Re: Local Pizzeria Closed.. Desperately need help to move fast w/my new Startup!](#)**2447**

My preferred method is to scale and ball immediately after mixing (finished dough temperature 70 to 75F), then lightly oil the dough balls and place into individual plastic food saver bags (they come on a roll and they're cheap) or use bread bags (they work great). Twist the open end into a pony tail and tuck it under the dough ball as you place it into the fridge, allow to cold ferment for 48-hours, remove from fridge and allow to temper AT room temperature for about 2-hours, then begin to open into skins. There is currently a video of Norma opening a dough ball and it shows her using this method to store the dough balls on the board.

[Re: tough dough](#)**2448**

Zing;

I can't speak for your local P.H. but for most box chain stores they are hung up on short baking times. For example, PJ's would have a pretty decent product IF they would just bake it 30-seconds longer....doesn't sound like much but it's a lot in an air impingement oven. If we add to that the fact that in a lot of stores they pull the pizza off of the conveyor before it fully exits the baking chamber and you have the stage set for a less than ideal finished crust under the pizza. Next time you go there go during a slack time 3:00 p.m. in the afternoon, and ask them to give the pizza a little more bake time by pushing the pizza back into the oven then see if it's any better.

[Re: Can You Still Get A Decent Pizza Hut Thin 'N Crispy Pie](#)**2449**

There is a good probability that the dough balls are not sufficiently relaxed after

being balled by your process. You might try balling the dough at least 10-hours prior to when you plan on opening them into skins, when you ball the dough after a fermentation period it really takes quite a bit of time for the dough to completely relax again.

[Re: tough dough](#)**2450**

Why not use the silicone baking sheets? Be sure to buy the heavier weight ones. We use them for making everything from brownies to focaccia and have never had a problem, all of the commercial focaccia lines use the same material but on a roll as opposed to individual sheets.

[Re: Silicone baking sheets](#)**2451**

Unless you want the pizzas to look like they have melted plastic on them I suggest going with the humidified cabinet warmer. Your maximum holding time should be around 2.5-hours or less.

[Re: Best countertop warmer?](#)**2452**

Very little multiplication of the yeast in a dough system but greater amount of yeast will result in faster fermentation. The amount of yeast used will, to a great extent, be determined upon how the dough is managed. By adding the ADY dry as you are will result in some of the glutathione leaching out of the yeast cells as well as creating a situation where the yeast can begin to cannibalize itself due to not being uniformly distributed throughout the dough (if you can pick through the dough and find small particles of ADY you likely are experiencing this problem). This potential loss of activity could be responsible for what appears to be a lack of oven spring with your dough.

[Re: Stretching Pizza Dough](#)**2453**

Assuming a total dough formula percent of 170, one pound of flour will make approximately $1.7 \times 16 = 27.2$ -ounces of dough. Assuming 10-ounces of dough for a 12-inch pizza $27.2 \div 10 = 2.72$, 12-inch pizzas can be made from one pound of flour. Or to put it another way, after accounting for bowl loss, from one pound of flour you will have sufficient dough to make two 12-inch pizzas and one 8-inch pizza.

[Re: How many 12 in pizzas per pound?](#)**2454**

Cool!

[Re: Affordable, HIGH QUALITY Artisan Dough Sheeters starting at 350.00 - see video](#)**2455**

I didn't see where you are activating the ADY in a small portion of 100F water, did I miss that?

[Re: Stretching Pizza Dough](#)**2456**

Flour has four main parts, moisture (about 12 to 13%), bran (about 5 to 7%), starch (about 70%) and protein (about 12 to 14%) we're talking about typical flours used for making pizza. Starch raw, intact starch has very little absorption properties (try adding some corn starch to water in an attempt to thicken it and you'll see what I mean), so it is the protein which exhibits almost all of the absorption properties in the flour, as the amount of protein in the flour goes up or down the dough absorption typically follows a similar trend. You can see this first hand by hydrating some vital wheat gluten (purified gluten from a flour based dough), it will have a very high absorption capacity.

[Re: chewy pizza](#)**2457**

Hopefully not rubbing alcohol! :(

The by products of yeast fermentation are:

Carbon dioxide

Acids (acetic, lactic and propionic are the main acids formed)

Alcohol (that's what you're smelling, just a normal by-product of fermentation which is more evident in a liquid or more liquid environment than in a dough as the alcohol is lost more readily to the air as opposed to being entrapped in the dough matrix).

[Re: Poolish smells like Alcohol](#)**2458**

Werty20;

Higher protein flour will typically require a higher dough absorption with all things equal.

[Re: chewy pizza](#)**2459**

Joe;

I forgot to add, you say you are allowing the dough balls to warm for several hours before opening it into skins, this might also be part of your problem, they only need to be allowed to warm to 50 to 60F range before opening. In most pizzerias they use 50 to 55F as their target temperature before they begin opening the dough balls. Note: This is internal dough ball temperature, not the surface temperature.

[Re: Stretching Pizza Dough](#)**2460**

Joe;

If the dough is handling OK and you're just getting thin spots and holes in the center section it's probably just your technique. I developed a method for training new hires how to open pizza skins by hand when they have little or no prior experience. Once you begin using the technique you will soon automatically begin to master the technique of opening your dough balls into skins. Do what you are doing, but when you go to open the dough balls do so using a rolling pin (remember to NEVER allow the barrel to roll off of the skin), open the dough to within about 2-inches of the desired finished diameter, then finish opening the dough by hand to the full diameter. This procedure works like a charm and soon you will be putting the rolling pin away and opening the entire dough ball by hand without those holes and thin spots. I've got a video of the process being used in AJ's New York Pizzeria, here in Manhattan, KS that I'll be glad to share with you, just P.M. me with your request for the AJ's video and give me an email address where I can send it to.

[Re: Stretching Pizza Dough](#)**2461**

Werty20;

From what I am seeing it looks like a pretty typical hand kneaded dough, the gassy appearance shown in the last photo is common to an under mixed dough, with that said, the pizza looks pretty good.

[Re: chewy pizza](#)**2462**

Pizza Hut, for many years, has used very generous amounts of oil in their deep-dish pans (peanut oil) to achieve a unique fried effect as opposed to a baked effect which you get using a plastic fat such as Crisco. Many of us here use a commercial garlic infused oil in their deep-dish pizza pans, or my favorite is a commercial garlic infused butter oil, which from your description sounds like what you might

be looking for, or you can make one yourself by adding garlic powder to an oil. When garlic is added TO the dough it has a softening effect upon the dough in much the same manner as L-cysteine/PZ-44 softens/relaxes the dough. This has been covered a number of time here if you want to read more about it.

If you want to have a softer, chewier finished crust with your deep-dish pizza the first thing I might try is just letting the pizza set in the pan for a minute or two after baking, this will drive much of the moisture from the pizza back into the pizza making it softer, chewier and somewhat tougher. Remember, oil/fat IN the dough formula is a tenderizer so if you delete the fat from the dough formula you will be moving the eating/mastication properties of the finished crust towards a more chewy characteristic if that's what you are looking for.

[Re: Oiling the pan with garlic oil](#)**2463**

Pictures of the finished pizza/crust would help in this case (be sure to show a picture of an inverted slice too so we can see what the bottom looks like. Aside from that, you say you are getting a smooth and soft dough after only 2 to 3-minutes of hand kneading.....are you sure about this? Even machine mixing takes more than twice this long to achieve the desired dough characteristics. I see that you are using IDY but you don't indicate that you are suspending it in 95F water prior to addition to the dough. IDY should only be added dry when machine mixing. You indicate that you allow the dough to rise until doubled or more, can you put a time on how long this is taking? The more information we have the better.

[Re: chewy pizza](#)**2464**

Just a short time back we had a lot of discussion on just such a topic (Detroit style pizza pans, steel ones too) If I remember correctly there was even a reference as to where they might be available, maybe Peter can work his magic and help dig it out.

[Re: Sicilian/Grandma's Pan](#)**2465**

I think it all started when kids began spending more time at the television, and then their computers and games than playing outside. I think the only part of the body being exercised by kids anymore is the thumbs. Society has also changed, and not for the better, parents are working when kids come home from school, kids eat junk food to hold them over until parents come home, all too often with a prepared meal such as pizza, fried chicken, etc., what ever happened to the vegetables and salads that we used to get at every dinner when I was a kid? Define a "snack", when I was a kid it was defined as an orange, apple, maybe some grapes, or a banana, how does that hold up to the modern definition? The situation isn't much better for breakfast either, pre-sweetened cereal, toaster pops, if you do a calorie count against what kids eat for breakfast today (if they even eat breakfast...that's another story) an egg, piece of toast, glass of milk and a piece of fruit or small glass of juice doesn't look too bad, but too many parents don't have time for preparing such things anymore. With adults portion control is a little understood concept or the concept they have is grossly distorted, take for example, what constitutes a serving of pasta? What is a serving of steak? What is a bowl of cereal? Add to that: Would you like to supersize that for \$1.00 more? Nuff said!

[Re: Pizzas must shrink or lose their toppings under Government anti-obesity plan](#)**2466**

Be cautious when using a ZipLock bag as the pressure developed by the fermenting dough can pop the bag open as this type of bag doesn't allow the bag to burp itself as a bread bag does, additionally, you seldom get full contact around the entire dough ball when using a ZL bag and those areas where the bag is not contacting

the dough is a place where you can get condensation forming resulting in a wet spot on the dough which usually leads to a bubble formation during baking as the moisture is vaporized. Bread bags or food saver bags are also dirt cheap, and if you're like me, you will reuse them several times making them "cheaper than dirt". I just roll-up my oily, used bread bags and stuff them into a repurposed soft spread margarine container and store them in the fridge.

[**Re: Yeast**](#)**2467**

It's used in the baking industry, if you contact a n ingredient supplier, like Watson Foods I'm sure they would have it. There is also a product called Butter Buds that you might be able to get at your local supermarket or I know for sure you can buy it on the Internet, just Google "Butter Buds".

[**Re: Butter Powder in deep dish dough**](#)**2468**

My "burning" questions are do you bake your raw dough pizzas on a steel or stone, or just on a pan, what is your dough formula, what kind of pizza are you making, and what is the dough ball weight? No such thing as TMI here. :)

[**Re: Oven Rack Heights?**](#)**2469**

Actually, the dough balls look perfect for the times indicated. What were you anticipating? If you reduce the IDY the dough may not be fully ready to use in 24-hours but instead most likely closer to 48-hours. Most pizzerias want to be able to use the dough on the day after it's made and still be able to use it at 48 to 72-hours. That's what that specific dough formula and procedure were designed for but like most things you can modify it to meet your specific needs. If you want to target a dough that will be better to use at 72-hours my recommendation is to just reduce the targeted finished dough temperature (75 to 80F range). If you reduce the yeast level there is always a possibility that you can get into a situation where you begin to reduce the oven spring properties of the dough which then opens a "Pandora's Box" of dough issues, the biggest of which is the development of the "dreaded gum line", followed by reduction of crumb porosity, loss of crispiness or crust turns soft soon after baking, toughness/chewiness, even bottom crust color issues can be experienced, like I said.....Pandora's Box.

[**Re: I've been playing around with The Dough Doctor's dough recipe...**](#)

[**Thoughts???**](#)**2470**

The dough management procedure that I use most when making pizzas at home is as follows:

- 1) Weigh water into bowl, add flour, salt, sugar (if used), and IDY (in a suspension with a small amount of 95F water).
- 2) Using a wooden spoon, stir until well blended.
- 3) Using a plastic scraper, transfer the dough to a well oiled bowl.
- 4) Drape with a piece of plastic and allow to ferment at room temperature for 2-hours.
- 5) Turn dough out of the bowl onto a flour surface and knead for about 2-minutes.
- 6) Scale into desired weight pieces (11-ounces).
- 7) Form each piece into a ball, oil each dough ball and place into individual bags (bread bags).
- 8) Twist the open end of the bag into a pony tail and tuck it under the dough ball as it is placed into the fridge.
- 9) Allow to cold ferment for 18 to 24-hours or as long as 48-hours.
- 10) Remove from fridge and allow to temper AT room temperature for about 2-hours (dough temperature 60F).

11) Roll bag down onto the dough ball and invert the bag over a floured surface allowing the dough ball to fall free from the bag.

12) Dust the dough ball well and open into a pizza skin for immediate dressing.

[Re: Dough Fermentation Process](#)2471

The more dense something is the better it will conduct heat (have better heat transfer properties) so yes, it is possible that cutting the loaf in half might help a bit as this would allow for a faster trip through that critical temperature zone for accelerated staling. This is the same reason why if we form our dough balls into a puck shape by flattening them slightly they will cool or freeze more efficiently (less cross section).

When we make croutons commercially we use a lean formulation bread (low in fat and sugar), then give it a long, slow bake (25 to 30-minutes at 400F), the bread is depanned and allowed to cool, it is then placed on racks and stored in a cooler (40F) overnight, on the following day the bread is sliced, lightly toasted, passed through a cube slicer, run through a cone shaped tumbler where they are sprayed with oil and a seasoning is added, after tumbling the croutons proceed directly to packaging (M.A.P. is generally used to protect the flavor and prevent development of rancidity).

[Re: Freezer to croutons](#)2472

OK...That does it!!! No more late night/VERY early morning posting by me, when I can't even spell my own name right (been practicing that for over 70-years too) you know it's time for me to hit the sack! :-D :-D :-D

[Re: need more crackle](#)2473

There are several things at work here;

1) You should never allow the bread to thoroughly cool prior to freezing, instead, it should be cooled to an internal temperature of 100F and not more than 105F, then wrapped snugly so as to eliminate any head space around the product.

2) A home freezer is about the slowest way to freeze anything known to man outside of an oven. What this means is that the bread is being very S L O W L Y frozen which means that it is passing through the critical temperature zone for staling (60 to 20F) at a very slow rate, the wrapping material applied slows it even more. All of this equals stale bread within the first 24-hours and one of the characteristics of stale bread is the firmness of the crumb structure (this is due to a characteristic of the wheat starch as it retrogrades during cooling) and aside from adding a commercial bread softener not too much can be done to prevent it, but reheating it TEMPORARILY reverses the staling for a few minutes. The addition of 5 to 10% mashed potatoes can help a little but it is not a "silver bullet".

3) The stretch wrap materials which we have available to us generally do not provide a sufficient moisture transfer barrier to prevent desiccation during the freezing process and the time the product is held in the freezer.

4) The average home freezer today has an Energy Star rating, to achieve this rating (improve operating efficiency) the freezer is designed to go through as many as 20 defrost cycles during a 24-hour period which makes freezer burn/desiccation a sure thing, and it certainly doesn't help the freezing rate by any stretch of the imagination.

5) It is well recognized that the more a product is baked the more severe the crumb firming due to the staling process will be, in fact, many of the bread softeners/anti staling agents, are essentially ineffective if the bread is baked more than 20-minutes at 425 to 450F.

6) Additionally, keep in mind that the larger the product (greater cross section) the

more difficult it becomes to effectively freeze the product. This is why we find many times that smaller items such as buns and rolls will tolerate freezing better than larger items like a loaf of bread.

7) I should also add that the ideal temperature for slacking-out/thawing frozen bread products, be it bread, rolls or buns is 105 to 110F with a relative humidity of 75 to 78%. This temperature and humidity affords the fastest thaw while still allowing time for moisture to equilibrate throughout the crumb (moisture migrated from the center of the crumb to an area closer to the crust during frozen storage). If the product is thawed too fast a wet, soggy product will be experienced, if it is thawed at a slower rate additional crumb staling will result as the product passes through the critical temperature range for crumb staling as it warms up.

[Re: Freezer to croutons](#)2474

Peter;

Duhhh! :-D

I must have been too tired when responding either that or I need to clean my glasses more often!

[Re: need more crackle](#)2475

If you could provide your dough formula and dough management procedure it would help a lot. Also tell us what you can about your oven and how you bake your pizzas. With the limited information provided 50% absorption is rather low for a neo pizza. Is there a specific reason why you are using such a low absorption?

Tom Lehmasnn/The Dough Doctor

[Re: need more crackle](#)2476

From the outward appearance I'd say it looks remotely like a Chicago style thin crust but with all that thick, heave sauce it sure ain't, plus Chicago thins are nowhere near 1 to 1.25-inches thick! That thickness qualifies it as a thick crust pizza in my book. Using a screen to bake in a deck oven significantly slows the baking which accounts for the oven spring creating the thicker crust and considering the amount of sauce and cheese I'd say it probable needs all the bake time it can get and from the color I'd say it's getting it. Aside fro that, I can't really see much of the crust or tell anything about it. My suggestion would be to start with a typical N.Y style dough, adjust the thickness so when baked, after being formed using a pie pin or rolling pin you get something close to the desired thickness. Baking temperature will most likely be about 500F. From this benchmark you can begin to make incremental adjustments to achieve what you feel are the desired crust characteristics.

Get ready to eat some pizza!

[Re: Replicating a bygone local classic, starting with the dough](#)2477

Come to think of it, it did kinda look like a large over fermented dough, didn't it?

:-D

While I'm sure many yeasts are genetically modified in some way (we're essentially all genetically modified, I'm the result of a German mother and an Italian father) but most yeasts are cultured, a strain having a desirable characteristic is cultured/propagated until the characteristic is dominant, it's then set aside for future reference of bottled for sale. I know that's how they came up with a variety of yeast specifically for freezing applications, a strain having a thicker than normal cell wall was identified and cultured and is now being sold (SAF/Green Label) for freezing applications where it demonstrates a slight advantage over conventional strains of bakers yeast.

[Re: Vacuum Sealing Frozen Dough Balls](#)**2478**

About a year ago I bought one from HF and my son liked it so much I gave it to him and went back and bought another one for myself. Paid \$15.00 each, then right after that Manard's had them on sale for \$11.00 each so, not to pass up a good deal I bought one of those too, so far all three are batting 1000. When I was at AIB I bought my first one for \$225.00!!!

[Re: My new toy](#)**2479**

Just as a FYI, you will be able to say you heard it here first, there is a new type of yeast being trialed right now as I type this that will change the whole complexion of dough storage as we presently know it. I have samples of it and it really works as it is designed to work. This new yeast is used just like any other IDY BUT it STOPS FERMENTING and essentially goes dormant when the internal dough temperature reaches 45F, then, after it is warmed back up to a temperature over 45F it resumes normal feeding/fermentation activity just as if nothing had ever happened...kinda mind blowing, isn't it! I'll be talking more about it as soon as I have approval to "let the cat out of the bag".

Hang in there, help is on the way!

[Re: Vacuum Sealing Frozen Dough Balls](#)**2480**

The big commercial frozen dough manufacturers target a 19 to 21-week shelf life on their frozen dough, to get this they employ little or no fermentation prior to freezing, mechanically blast freeze at -20 to -35F with an airflow of 600 to 800 linear feet per minute over the product, then then place the dough into a holding freezer at -10F for 24-hours prior to shipping. The dough can also be cryogenically frozen using an industrial cryogen (liquid carbon dioxide or liquid nitrogen) at a temperature in the product zone of -55 to -65F, this will shell freeze the dough so it must go through an equilibration period in the holding freezer (90-minutes) for the temperature to equilibrate throughout the dough. They look for an equilibration temperature of +10 to +15F. The dwell time in the cryogenic freezer is adjusted to achieve the targeted equilibrated dough temperature. The dough is held in the holding freezer for 24-hours prior to shipping. Since temperature fluctuations and thawing are the main issues to achieving long frozen dough shelf life great detail is paid to shipping, warehousing and distribution of commercially made frozen dough. Most go so far as to own and operate their own fleet of delivery trucks/"reefers". Using static freezing (walk-in freezer/0 to -10F) with little to no airflow, about the best one can hope for is six weeks before dough performance begins to get spotty, which is not a big deal if you're making pizzas at home, but it is a big deal if you are a restaurant, hotel or pizzeria and you have freezer full of the stuff and it's failing.

[Re: Vacuum Sealing Frozen Dough Balls](#)**2481**

Since it's not the air, but instead the slow freezing rate and the constant temperature fluctuation in a home freezer (and you paid extra for that 5 Energy Star rating) that impacts the shelf life. Home freezers (especially the more efficient ones) will go through as many as 20 defrost cycles in a 24-hour period which is disastrous for the dough, or should I say the yeast.

[Re: Vacuum Sealing Frozen Dough Balls](#)**2482**

I'm in total agreement with Steve, Spiral mixer, dough divider/rounder, plus an additional rounder so you can double round the dough balls. From there you will need to have a walk-in cooler/retarder sized to hold at least 65 to 70-dough boxes

minimum (assuming 8-dough balls per box) also make sure you will have sufficient room to cross-stack the dough boxes. Assuming 10 dough boxes in a stack you will be inventorying about 6 to 8 stacks of boxes, allow a little more than double that space for cross-stacking. You will also need to have a delivery vehicle for transporting the dough balls from your "commissary" to the event. You will need to have refrigeration at the event too for holding dough, sauce, cheese and toppings. Your local health department will spell out everything else you will need to have in place both at the commissary and the event.

[Re: Co-packer Commercial Bakery for your Dough Balls? 2483](#)

Irishboy;

There is little to no perceptible difference in fermentation rate of finished product flavor resulting from the use of ADY, IDY or CY when used at the correct substitution levels and assuming all are of good quality and haven't been time or temperature abused in any way. As for ADY, yes, it REALLY does need to be suspended in warm (100 to not more than 105F/37.7 to 40.5C) water for about 10-minutes prior to addition to the dough. Unlike IDY, ADY is somewhat difficult to hydrate properly which is why it must be suspended in warm water prior to use. IDY is designed to hydrate much easier/faster (which is where the "instant" comes from), as in instant hydrating so it can be added directly to the flour or if desired to the dough mass about 4 to 5-minutes prior to the completion of the mixing cycle.

[Re: Yeast 2484](#)

Well done! Not too shabby!! All things considered. :)

[Re: what is the correct process for 72 cold bulk 2485](#)

First of all, frozen pizza right out of the freezer isn't all that great :-D but after being reconed/reheated for serving, it can be pretty decent. I think what you are asking is can one make a frozen pizza using a par-baked crust which when reheated for serving is on par with a pizzeria quality pizza? Done properly, and reheated correctly I think you can get quality within the range of that from a pizzeria, remember though that pizzeria quality is literally all over the board and also since quality is highly subjective what one person thinks is great another may find it to be not so great. So let's just say this, yes you can make a decent quality frozen pizza using a par-baked crust but only if it's done correctly and consumed while still hot/warm after being baked for serving.

[Re: Restaurant Quality Frozen Pizza 2486](#)

Can you make bread with the dough? Sure, scale, ball, place on lightly oiled pan (a cake pan works well) and cover with a large bowl (I like to place a wet/damp towel under the cake pan as it will provide humidity to the proofing dough) allow to proof, cut a few docking slits in the top of the ball, spritz with water and bake at 400/425F until golden brown.

Yes, you can freeze the dough but only for a week or so.

[Re: what is the correct process for 72 cold bulk 2487](#)

The direction provided by Norcosia is spot-on. But as it sounds like you are already into the process, do not delay, remove the dough from the fridge, scale into desired weight pieces and form into balls, then allow the dough balls to sit out at room temperature (cover with a sheet of plastic to prevent drying) until they are sufficiently soft and pliable to be opened into skins for immediate use, or if you are three to five hours out from using the dough just scale, ball, oil the dough balls and place into individual plastic bags (bread bags work well, very well) twist the open

end into a pony tail and tuck it under the dough ball as you place it on the counter top, then set aside to ferment at room temperature until ready to use. To remove the dough from the bag just roll the bag down around the dough ball, and invert the bag allowing the dough to strip itself out of the bag falling onto a well dusted surface, open into a skin by your preferred manner.

[Re: what is the correct process for 72 cold bulk 2488](#)

Believe it or not, adding the IDY (in dry form) to the mixed dough is actually the manufacturer's recommended way to add the IDY, so no harm was done.

[Re: Forgot to add idy 2489](#)

Yael;

When making pizza we open the dough ball into a "skin" which is ultimately topped with sauce and dressed to the order to make a pizza, but when making bread we usually just bake the dough from a round ball shape, or we can flatten it slightly and roll it into shape as when making Italian bread, French bread or baguettes. When making a typical American or British pan bread the dough is rolled flat, about 1/4-inch thick and then rolled (like a jelly roll) into a loaf shape which will be final proofed and baked to make the customary loaf.

[Re: My first attempt at no-knead bread 2490](#)

Did you ever look at the deck of a commercial pizza oven? Yep, I agree totally with Craig.

[Re: Ruined? 2491](#)

James;

Some time ago I wrote an article in Pizza Today Magazine on the impact of using different methods to open the dough on characteristics of the finished crust. You might be able to find this article in their archives. Using a dough roller/sheeter will have somewhat of a degassing effect upon the dough as compared to the other methods of opening the dough, especially opening by hand. The end result is typically a thinner, more dense/compact crumb structure. As for the problems you are experiencing running the dough through the sheeter, I offer the following:

- 1) Are you allowing the dough to warm up to at least 55 to 60F before trying the sheet it?
- 2) Are you using multiple passes through the sheeting rolls to open the dough? Typically four or more passes are required with one or two adjustments made to the thickness setting.
- 3) Are you dusting the dough ball with dusting flour before sheeting it?
- 4) Check to make sure the dough is sufficiently relaxed prior to sheeting, you can do this by simply pressing down on the dough ball, if it feels firm and springs right back sheeting will be less than desirable, but if it can be easily pressed and deflates slightly it should be sufficiently relaxed for decent sheeting properties.

A number of years ago I developed a method for opening the dough using both the sheeter (to pre-open the dough to within 2 to 3-inches of full diameter and then finishing the opening by hand to full diameter. This method results in faster, more consistent opening of the dough with the added benefit that you don't get a thin center section in the opened skin (common to many skins opened entirely by hand, especially if opened by someone without a lot of experience in hand opening dough. I have a video showing this process in actual use in a pizzeria, if you would like to see a copy of the video just email me at <thedoughdoctor@hotmail.com> and I'll be glad to share it with you.

[Re: Naughty words - dough roller...and hydration rates...2492](#)

If the guy has Hep. or some other communicable disease I think it might be viewed the same as AIDS by the courts. Then too, it appears that the spit was applied prior to baking so it might be argued that any pathogens would be destroyed during the baking process, Dirty Harry had the right response to that "Do ya feel lucky?"

[Re: I'll pass on that first ingredient2493](#)

Yep, that's how pita is made. Try this instead, apply 1/2 of the sauce to the skin just before placing it in the oven to par bake, this should help address the problem, you can also dock the dough with a blunt shaped dough docker.

[Re: Dough bubbling up2494](#)

If you'll remember back a number of years ago when we were seeing all sorts of food tampering (glass in baby food, rat poison in Tylenol, nail polish remover in bread, etc.) Now those days are pretty well gone because of the Federal mandated sentencing guidelines for food tampering...20-years, no give or take. If you're found guilty, by, by for 20-years! This guy could be in for a BIG HURT if they decide to go after him on this, which, in all probability, they will if he doesn't pass a health test with flying colors.

[Re: I'll pass on that first ingredient2495](#)

Yael:

When making dough by this process and using IDY, the IDY should first be suspended in a small amount of water at 95F/35C, and then added into the remainder of the dough water. Failure to do so can result in erratic results. Once biochemical fermentation does its thing you should be able to scrape the dough out of its container and form it into a ball, then allow the ball to rest at room temperature until it can be easily opened into a skin (this usually takes about 3-hours).

[Re: My first attempt at no-knead bread2496](#)

Several years ago I was invited to spend a few days with Stanislaus during the tomato harvest to see first hand how they're harvested and processed. If anyone ever gets an invitation don't hesitate to accept it. They only harvest the fields but once, then the remainder of the crop is sold to another processor mostly for picante sauce.

[Re: In the Stanislaus fields with Steve Rouse2497](#)

Is the IDY that you are using fresh, like from a recently opened package or has it been in some type of storage a for a while? I have done a huge amount of research on IDY since the late 1960's when Fermipan, then SAF first came into this country. Included in this research were studies to determine how well it held up to long term storage under various conditions...remember, at that time a 2-year shelf life was unheard of for any kind of yeast. What we found was that unopened packages (vacuum packaged) were good for at least a full year if held refrigerated, frozen or in a cool environment (70F), after two years we began to see spotty results with some samples showing a loss of as much as 25% gassing power. After the packages were opened the yeast showed much less tolerance to storage temperature, so much so that we would see a change in gassing power after as few as 3-weeks storage at ambient temperature storage when refrigerated or frozen another week or two could be added before we saw changes taking place. Here's the "kicker" in

home use of IDY. When stored in the fridge or freezer every time you open the storage container you allow air to enter and contact the yeast, this air is warm and contains moisture which now condenses on the cold yeast (moisture is the #1 enemy of IDY) this leads to deterioration of the IDY as it is repeated every time the container is opened. This is why we do not recommend storing opened IDY for more than just a few weeks as the performance of the IDY cannot be predicted after that time. Actually, if you are going to store opened IDY, place it into a small plastic bag where you can reduce/eliminate any head space, close it tightly and store it at room temperature, this eliminates the condensation issue and depending upon local humidity conditions should give you 6-weeks or more usable shelf life for the IDY. When IDY begins to deteriorate you will begin to see the doughs getting slack/soft and not rising as expected for the amount of IDY being used. This is why I have raised the question regarding the age of your IDY.

Additionally, you might just try increasing the amount of IDY, if the doughs seem to get even softer and still don't rise properly you've got a pretty good idea of what might have happened if any of this applies to you.

[**Re: Bulk Fermentation.**](#) **2498**

Once the dough has been fermented it is gassy and porous/less dense so it becomes an excellent insulator, as such it is hard to darn near impossible to change the temperature of the dough within a meaningful period of time, add to that the fact that you also have heat of metabolism to contend with (dough is generating heat at the rate of approximately 1F per hour). So, what to do? I would consider degassing the dough and re-ball it, then as soon as possible flatten the dough ball into something of a "puck" (like a hockey puck) shape as this will reduce the cross section of the dough piece allowing for more efficient cooling. To promote better heat transfer I would think about placing the dough puck into a plastic bag rather than a box or bowl as the thin plastic will afford better heat transfer properties. I would think you should be able to eek out an additional 24 to 48-hours by doing something along these lines.

[**Re: Slow down dough 50-100% into fermentation?**](#) **2499**

We always trained our students in assembling the pizza in a manner similar to the appearance of a volcano where there are more toppings applied around the circumference (especially cheese and sauce) than in the center of the skin. This allows for a better bake in the center of the pizza. Don't worry about the distribution of the toppings, as the pizza bakes the sauce and toppings will naturally flow towards the center as the edges of the skin begin to rise during the oven spring period of baking. There is also a strong tendency to get the center of the skin too thin as the dough ball is being opened, this results in excessive heat transfer through the dough (discussed in detail previously) resulting in a finished crust in the center section with less than an ideal bake which results in a soft, limp center to the baked pizza and droopy slices.

[**Re: 550 degree home oven vs 600 degree pizza oven**](#) **2500**

I forgot to add that the bagged dough in the pictures does not appear to have had the bad pulled down around the dough ball prior to closing the bag. When correctly bagged you won't see the corners of the bag inflating with gas. There is also a possibility that the bag(s) were too large which would also result in this happening. I have found that bread bags, whether new or reused are about the right size for all but the smallest dough balls. I tried bun bags (like hamburger and hot dog buns come in) and I had a similar issue with the corners of the bag as they are a wider bag.

[Re: Problem with dough not staying in a ball shape - do i need to reball?2501](#)

With that much fermentation on the poolish it is going to be quite acid which is not good for the gluten forming proteins as they are broken down by both the acids formed during fermentation and the enzymes which are present in both the yeast and the flour, much of the starch will be hydrolyzed into sugars to support fermentation so what's left in the poolish aside from the water? Just my estimation. So now we just take into account the water in the poolish for formulation purposes and maybe the yeast. But if the yeast runs out of nutrient to feed upon it will begin to cannibalize itself which will release glutathione into the system (remember glutathione is just like L-cysteine) making for a very slack, sticky dough characteristic.

I'm not saying it's so, that's just how I see it in my mind's eye not having seen the dough or the entire process. Call it an educated S.W.A.G.

[Re: Problem with dough not staying in a ball shape - do i need to reball?2502](#)

Balancer flour is lower in protein content than All Trumps flour, so all things being equal one could expect that the lower protein flour would provide a less chewy finished crust characteristic.

[Re: Balancer?2503](#)

After 18-hours fermentation you should not be including the flour in the poolish in with the dough flour as it is essentially non functional as a structure builder (strengthener) in the dough. So, unless I've missed something, this is what I'm looking at here: warm water + ice = 280-grams + 45 grams in the poolish for a total of 325-grams of water. Total flour (excluding the flour in the poolish) = 353-grams. Total absorption (325 divided by 353 X 100) = 92% dough absorption.

[Re: Problem with dough not staying in a ball shape - do i need to reball?2504](#)

In your reference to the yeast you say 0.034 @ 70F. would you please explain what you mean by this?

[Re: Bulk Fermentation.2505](#)

Yay;

To calculate the dough absorption just divide the weight of the water added to the dough by the weight of the total flour and multiply by 100. If you provide us with the flour weight as well as the weight of the water you added to the dough we can do the calculation for you.

[Re: Problem with dough not staying in a ball shape - do i need to reball?2506](#)

In view of the "J" hook I'm guessing that your dough might be under mixed which by itself results in a sticky dough. Maybe follow up on the machine mixing with some hand kneading before doing the bulk fermentation.

[Re: Bulk Fermentation.2507](#)

One trick to finding good hardwood is in locating a lumber mill and buying their trim scrap pieces. We used to buy it by the pick-up load for just a few dollars at a mill just outside of St. Paul, Arkansas. People down there buy it to feed their wood burning furnaces during the winter months.

[Re: Best types of wood for pizza ovens2508](#)

Actually...hydration rate is the rate that the flour absorbs the water, not the amount of water actually being absorbed. The temperature of the flour can have a

significant impact on the hydration rate of the flour with cold flour having a slower hydration rate than warm flour. This is why the Brabender Farinograph laboratory instrument for measuring both flour absorption and hydration rate) has a temperature controlled mixing bowl. Your math is spot-on! :) and your example explained it quite well.

[Re: Flour VWG protein calculator](#)**2509**

When we used wood fired ovens we used to use seasoned split oak exclusively.

[Re: Best types of wood for pizza ovens](#)**2510**

Three questions: What was the finished dough temperature? What was the total dough absorption? What was the temperature of the fridge?

[Re: Problem with dough not staying in a ball shape - do i need to reball?](#)**2511**

The water pooling in the corners of your fermentation containers is an indication of one of two things;

- 1) You are not leaving the containers uncovered long enough after placing them into the fridge.
- 2) You are not leaving the containers uncovered after placing them into the fridge. Physics 101, dough is warmer than the fridge, dough heats air trapped in the container, moisture moves from the dough to the warm air, container walls cool down causing moisture inside the container to condense against the container walls....gravity does the rest.

Pooled water in the container can cause problems such as sticky dough, extreme or excessive bubbling or dough sporadically sticking to the peel.

[Re: Kneading vs Tearing Dough in Mixer](#)**2512**

Straight mozzarella is pretty mild in flavor so if it's flavor you're looking for try blending it with another cheese. My personal favorite is to add a combination of Parmesan and Romano to augment the flavor of the mozzarella. If it's butter fat content you're looking for use straight provolone as it's higher in fat content than mozzarella but the flavor will not be all that different unless it's a smoked provolone.

[Re: Highest butterfat Low Moisture Whole Milk loaf Mozzarella cheese?](#)**2513**

Since pizza doughs are fermented for long periods of time the finished dough temperature is important in achieving a consistent quality dough as well as in preventing over fermented doughs. You mention that your dough appears to be over fermented, what is your finished dough temperature and how are you managing the dough after mixing?

You can add the CY just as it is, the mixer will disperse it throughout the dough it for you, or if you wish, you can make a yeast suspension using a small portion of the dough water. Either way works well.

[Re: Kneading vs Tearing Dough in Mixer](#)**2514**

I'd start at 65%, this will get you close enough to make minor adjustments as needed.

[Re: 00/bread flour mix: what percent hydration?](#)**2515**

What type of pizza are you wanting to make?

[Re: 00/bread flour mix: what percent hydration?](#)**2516**

The only way to get that pastry crust characteristic is to incorporate pieces of hard fat into the dough, much like making a long flake pie crust dough or folding in some way to get laminations.

Try this:

Refrigerate the flour overnight.

Add 10% butter or margarine (must also be refrigerated).

Cut the fat into the flour as one would when making a flaky pie crust dough.

Adjust dough absorption to 50%.

Use cold water right out of the fridge when making the dough.

Put salt, sugar and compressed yeast into the water and stir until the yeast is suspended.

Immediately add water to the flour-fat mixture.

Mix until a shaggy dough is achieved. DO NOT OVER MIX.

Scale to desired weight and form into puck shape.

Place into individual plastic food bags, twist to close and place into fridge to CF for at least 48-hours.

Remove from fridge, allow the temper to 50F and roll out (does not open by hand well at all) using a rolling pin or pastry pin to desired thickness, trim to round shape, dock, dress and bake.

[Re: Pie/croissant - like dough - no solution via forum](#)2517

The only way vital wheat gluten can be added is to dry blend it into the flour. DO NOT allow the VWG to come into direct contact with water as this will cause it to "pill" (form lumps) which are next to impossibly to work out. When dispersed into the dry flour the gluten will hydrate normally right along with the flour.

[Re: Adding gluten to low-protein flour?](#)2518

When storing pre-opened pizza skins we typically place them individually onto pizza screens and place into the cooler on a wire tree rack for at least 30 to 45-minutes to thoroughly chill, then place a piece of silicone paper on a screen and place one of the chilled skins on the paper, place another skin on that paper and another skin, build a stack not more than 5 high, place back onto the wire tree rack and cover with a plastic bag.

[Re: In a commercial setting...](#)2519

A good place to start would be to get an electronic scale (quite economical) and begin scaling your ingredients so you know what you have for a dough and this will also allow you to make meaningful changes and follow the changes in the dough to achieve the dough characteristics you're looking for. Additionally, don't allow the dough to warm to room temperature after the CF period, instead, allow it to come to 55 to 60F before you begin opening the dough into pizza skins, this step alone may significantly change the way your dough handles.

[Re: Dough and Oven Temp](#)2520

Very few people are looking for a yeast/yeasty flavor, instead what they are looking for is a fermentation flavor, as I correct in assuming this? (yeast has a lot of the flavor characteristics of old, wet newspaper). Your dough formula as well as dough management procedure would be very helpful in answering your question.

[Re: dough flavor](#)2521

If your dough absorption is up around 70% or higher an autolyse will certainly help in getting the water incorporated into the flour but if it's lower then that you probably will not see as much benefit when using a mechanical mixer...total hand

mixing yes, but as with what you have described, probably not too much benefit unless you have the high absorption. If it's just a "puffier" edge that you're looking for an increase in dough absorption will probably help as might an increase in yeast but I can't say for sure as I don't know what your dough formula or management procedure is. Anything which will improve/increase oven spring should be a move in the right direction for you.

[Re: Autolyse Question2522](#)

When it comes to pizza (specific to this response) taste, aroma (flavor = taste and aroma) as well as textural and mastication properties are all purely subjective and based on an individual's perception, for that reason I don't think there can be any "scientific" base line regarding these characteristics. It is well known that in some societies certain characteristics might be preferred over others such as in Japan where things that are tart (sour) and crispy (hard) have not historically been preferred....that is now changing as new "Western" foods are continually being introduced into Japan's culture. In northern Turkey, rancid yak butter is a delicacy and in Australia, Vegemite is still consumed but, admitted by most Australians that I've spoken to, is an "acquired" taste. Even here in the U.S. flavor and textural preferences are all over the board, so much so that Ragu has regional formulas for their Ragu sauce. About the best one can ever hope for is to identify specific regional preferences and even then it's far from accurate. The good news about all of this is that it forms the foundation upon which the popularity of pizza is built, there are many, many differences in pizza so there is something for everyone and add to that as a product ages in the market over time we begin looking for something a little different.....show of hands please, how many of us has NOT succumbed to that? Pizza is continually changing and evolving for the better or worse, so if you don't like one pizza there will always be another one that you enjoy. Don't get too hung up on flavor and texture, find what you like and concentrate on it, you're making it for YOU, so you can develop the pizza specific to your own likes and if you don't like it you know who to blame. Lastly, experiment, over time as our tastes change....yes, they do change, you may want to try something a little different and experimenting is an excellent way to make ourselves more informed, enlightened, and get some great pizza along the way for our trouble.

[Re: Natural leavening Questions2523](#)

Stickiness is generally an indication of either too much diastatic malt or the use of diastatic malt where a nondiastatic malt is called for. Darn near impossible to get rid of that stickiness too. The excessive softness is most likely due to excessive fermentation. If the stickiness persists try using a nondiastatic malt.

[Re: Sticky, dough too soft. Need help!2524](#)

The main purpose of the autolyse (flour + water) is to allow time for better flour hydration (absorption of water into the flour) which can be beneficial when making very high absorption doughs or mixing the dough by hand. Water at 70 to 75F is all that is needed, then adjust the temperature of the remaining water to give you a finished/mixed dough at the temperature you are targeting (usually around 75F but may vary).

[Re: Autolyse Question2525](#)

Any idea of the finished dough temperature? That will have a significant impact upon how much fermentation the dough is exposed to during any given period of time. Typically we look for a finished dough temperature in the 70 to 75F range. The dough that you got from the pizzeria most likely used a dough management

procedure similar to this: Mix (finished dough temperature (75 to 80F), immediately take to the bench for scaling and balling, place into dough boxes, oil the top of the dough balls, cross-stack in the cooler for at least 2.5-hours (variable with dough ball weight), down-stack and allow to cold ferment for 24 to 48-hours, remove from cooler and allow dough baslls to reach an internal temperature of 50F before opening into skins. The dough balls typically remain good to work with for a period of 2.5 to 3-hours after reaching 50F. (sound familiar?). The yeast level it usually around 0.3 to 0.4% ADY with a dough absorption of 63%.

[Re: Sticky, dough too soft. Need help!](#)**2526**

The question is was it a pastry crust (at one time Tony's/Schwan's Food Service/Frozen pizza) made pizzas using a laminated pastry type dough, or was it a cracker type crust? The shape of the crumb cells is a tip off as to which it was. The laminated pastry type crust will have elongated (football shaped holes, it's referred to as fish mouthing) while a cracker type crust will have round shaped cell structure. There is a huge difference between the two. Also, at one time some pizzerias were experimenting with sheeting the dough and folding into quarters (fold in half and then in half again) and giving it a final sheeting with 2 to 3 passes through the sheeter. This was typically done with a relatively low absorption (55 to 57%) dough while using a lower (10.7 to 11.2%) protein flour. Typical 48-hour CF dough was used. No roll-in was ever applied to these doughs.

To be more specific more information is really needed.

[Re: Pie/croissant - like dough - no solution via forum](#)**2527**

Much crust color development? As you need to reach temperatures in the 340 to 350F range for caramelization of sugars to take place how do you develop crust color at those low temperatures?

[Re: Stop them sticking!](#)**2528**

Temperature is the number one driver of fermentation, the colder the dough is the slower it will ferment and the warmer it is the faster it will ferment within any given period of time.

Also, warm dough will expand more freely than cold dough so even with all things equal the colder dough will be firmer and show less expansion than a warmer dough. This is why we suggest allowing the dough balls to warm-up a bit after removing them from the fridge before opening them into skins.

[Re: Dough expansion when fermenting](#)**2529**

Did the sausage bake up crispy like bacon? ;D

[Re: Stop them sticking!](#)**2530**

Keep your existing planetary mixer for everything else but the dough, once you use a spiral dough mixer there is no going back to a planetary mixer for mixing dough :).

[Re: Planetary vs. Spiral mixers](#)**2531**

Temperatures in the 65 to 75F range will support fermentation just fine so room temperature should work for you. 70% absorption seems a bit high for what you are planning to do. I'd suggest reducing the total dough absorption to 60% and then working up from there in 2% or 5% increments.

[Re: How Much Protein per 100gr for High Hydration Dough?](#)**2532**

I just came back from a training project where we made pizzas for the entire day.

We used my "go to" blend of equal parts of regular flour, fine corn meal and semolina flour and never had a pizza stick all day, and some of the dough balls that we were working with by the end of the day were past their prime and well over fermented with a burning desire to stick to something but none did when we were using that blend for our dusting flour and peel dust. All pizzas were dressed on a wood prep-peel and peeled into the oven off of the prep-peel.

Another thing that you can do is to dress the pizza on a well seasoned screen, place the pizza into the oven on the screen and after about 2-minutes (maybe a little less) you will be able to slide a metal peel under the pizza and lift it off of the screen and place it onto the deck to finish baking.

[Re: Stop them sticking!](#)**2533**

Additionally, we need to know how the flour was portioned by the cup, poured in and struck off level, sifter into the cup or scooped as all will have a different weight. Best thing is the the person to get an actual weight on the amount (3.5-cups) of flour they are using and go from there. Also, define "plain" flour". Knowing more about the flour would help too.

One other thing that might help would be to blend the ingredients together with a wood spoon and place it into a lightly oiled bowl to ferment for about 2-hours to get some biochemical gluten development before kneading the dough, or just fermenting the dough for several hours or overnight in the fridge to achieve full biochemical gluten development.

[Re: Look at this mess](#)**2534**

There are two ways to identify the presence of the dreaded gum line.

1) Cut a wedge from the pizza, grasping the wedge at the heel (crust/rim), pull it apart as if tearing it in two, if the crust cleaves cleanly, like a slice of bread being pulled apart you don't have a gum line. If it feathers (stretches and forms a film as it is pulled apart you have a gum line.

2) Turn the pizza slice upside down and using a razor blade or sharp box knife, carefully cut through the crust from heel to point, then fold so both cut surfaces are exposed (greasy sides together), if you have a gum line you will see a distinct gray area just below the sauce. If you see just a paper thin gray line, this is normal and you do not have a gum line. I normally do both tests to determine the presence or absence of a gum line. These tests are best done about 3 to 5-minutes after removing the pizza from the oven.

NOTE: DO NOT cut the pizza from the top to ascertain if a gum line is present or not. The sauce and cheese will be pulled down over the crumb portion and the crumb will be damaged as a result of cutting from the top which will make this an exercise in futility.

Pictures are the only way to make an accurate determination without actually having the pizza in ones hands.

[Re: Is this a gum line?](#)**2535**

50-years ago the baking industry was heavily invested in continuous mixing systems (batter whipped breads as they became known as) which required a very strong, high protein flour to function well so bakers pressured millers to go back to the plant breeders to develop higher protein wheat varieties with stronger gluten characteristics. Plant breeders responded and to some extent the protein content increased (I worked with experimentally grown HRW that was over 20% protein content and was so strong the gluten couldn't be developed in less than 30-minutes of high speed mixing (industry standard requires that the gluten be developed with 10 to 12-minutes of high speed mixing) needless to say these wheat varieties were

never released for planting. The result of the efforts by the plant breeders was only limited increase in protein content BUT something happened to the protein characteristics in that it became much stronger (I don't know if there is any correlation, but this is also in the same time frame that we begin to hear more about wheat protein allergies and gluten intolerance issues).

By the time this was happening the baking industry had gone away from the continuous mixing systems and had reverted back to the sponge and dough bread making processes which did not require the strong flours but due to their previous requests from many years earlier (it took 10 to 15-years to develop the new wheat varieties to produce the flour characteristics that the bakers were asking for) so now they were asking the wheat breeders to reverse the direction of the pendulum and develop less tenacious wheat varieties, but alas.....the genie was out of the bottle and the breeders were unable to eliminate the strong characteristic of the gluten from their new wheat varieties.

Back in the 50's and 60's a 10.5% protein HRW was considered to be an industrial wheat only good for non bakery applications but now they were said to be too strong! To this day I don't think anybody really knows what happened to the protein to result in the change that we saw. AIB developed a special group and studied it for well over 20-years with no success as did every university with a cereal science department.

Now, this is where the fun begins, much of the world population consumes rice but there is a world wide shortage of rice so those rice consuming countries have changed over to using greater amounts of wheat, this has been going on for many years now. This has resulted in a greater world demand for wheat, especially HRW#2, a very popular grade of export wheat from the U.S. so wheat acreage has gone up and wheat was planted where it normally would not grow but irrigation and fertilizer made it possible, now irrigation is more strictly regulated and fertilizer prices are out of sight cost wise as well as fuel prices to apply it, so wheat acreage has diminished over the years (corn has greatly replaced it) but the demand still remains so we are now fertilizing less acreage of wheat and the breeders are concentrating more on yield than baking properties as most of the wheat is exported anyhow, and what you now see is what you get.

Typically, as wheat yield goes up, the protein content goes down and vice versa. When I was heavily involved in wheat testing we used to say that the first priority of the wheat breeders was yield (agronomics) and the second was performance.....I think the same is still true today, as ever more land is lost for farming (how many new subdivisions have you seen where there used to be a farm field?) the emphasis will continue to be on yield over performance. Add to all of that, there might be some improved wheat varieties developed that will never see the light of day because that don't have the necessary resistance to drought, rust/fungal infections, or insect resistance. These are now all vital characteristics in new wheat varieties because we no longer have the chemicals needed to address these issues in the field so the resistance has to be bred into the variety prior to release for planting. You have heard me say it before but I'll say it again, one of my two heroes is the flour miller. Considering what they have to work with, they perform a near miracle in giving us the level of consistency we see in our flour. My other hero is Betty Crocker....have you ever see any of her cake mixes fail? :)

When we used to make emergency sourdough pizzas we used to double up on the amount of starter used and then spiked the dough with 1% compressed yeast or the equivalent of IDY or ADY, adjust the water temperature to give a finished dough temperature in the 85 to 90F range and we had a true "emergency dough" that went from mixer to oven in about 2 to 2.5-hours. This was developed for stores that might be working with a sourdough starter and needed dough in a hurry for whatever reason.

[Re: SD emergency pizza?2537](#)

Hummm, I've used the ice calculations for many years and it has always worked well for me. Remember, it works in "F" only not in "C". I used to have the calculations in "C" but I have no idea of where they might be now. Also, remember you will be replacing an equal amount (weight) of water with ice.

Maybe if you could show your math I might be able to see what the problem is.

[Re: Formula for water temp2538](#)

Actually, it sounds pretty good just as it is, but since I can never leave well enough alone I'd also add a few fresh onion and tomato slices and top with a light sprinkling of shredded Parmesan cheese. When I make my seafood pizzas I use a basic Alfredo sauce for the base which I make on the stove top by mixing Parmesan cheese and cream and gently heating until moderately thick and creamy (adjust viscosity by adding more cream if necessary) or if too thin add a bit more Parmesan cheese. I then add garlic and white pepper to taste. I use pre-cooked seafood but the fish is used raw. I thin slice it and place on the pizza letting the oven heat cook it for me. In addition to salmon you can use just about any firm flesh fish for a seafood pizza. If you search back in the archives here you will find some discussion on seafood pizzas which you may find of interest for different presentations.

[Re: Tarragon salmon pizza Question2539](#)

Most of those that I've worked with ferment the dough in large food safe containers at room temperature...yes, they do strive to achieve their targeted finished dough temperature. After the fermentation process they scale/ball and rest until the dough balls can be opened into skins. Some will hold the dough balls or skins under refrigeration (best results are achieved with the skins held under refrigeration as I've described).

If you have a spiral mixer you should be able to put the additional 15% scrap dough in right with your full size fresh dough but if you have a planetary mixer, unless you're mixing smaller size doughs already, you will need to adjust the total dough size so as not to overload the mixer.

[Re: In a commercial setting...2540](#)

That rest period between mixing and balling aka bulk fermentation is an optional step. I personally never use a rest period as it leads to too much inconsistency in the dough as a result of lack of temperature control if I should miss my target finished dough temperature. My preference is also for the flavor developed during cold fermentation as opposed to room temperature fermentation, but if you have a preference for the flavors developed using room temperature fermentation not a problem, work out a bulk fermentation time that works with your dough formula and finished dough temperature.

[Re: Is it necessary to rest the dough?2541](#)

Victor;

Easy to do, just manage the dough by your preferred procedure, as soon as you

open the dough balls into skins place them onto screens or some other suitable platform, immediately place in the retarder (commercial name for the fridge) on a wire tree rack, after 30-minutes in the retarder cover the tree racks with suitable plastic bags to prevent drying. The pre-opened skins will last all day. Depending upon your dough formulation you may be able to use the skins directly from the retarder or you might need to allow them to warm AT room temperature for a couple of minutes before dressing and baking. Before you ask, no, I am not saying to bake the pizzas on the screens, they serve only as a carrier in this case. I usually slip the skins off of the screen onto a wood prep peel, then adjust it a little using my hands and fingers prior to dressing the skin to the order and baking.

In most cases we can hold the pre-opened skins over night for FIFO use on the following day, this will depend upon how the dough performs on the following day (all formulas are different in this regard). In a worse case scenario you can add your scrap dough back to your new dough at a rate of up to 15% of the new dough weight, more than that and it will begin to impact the finished crust quality characteristics...remember, in a commercial setting consistency is the key to success.

[Re: In a commercial setting...2542](#)

I don't like "recipes" since they're based on volumetric portions. When I see a "recipe" that looks interesting to me the first thing I do is to convert it to a "formula" based on weight measures, that way I can accurately replicate it if I want to or if necessary (more often than not) I can easily manipulate the ingredients to give me something based on my specific likes.

I am not too "hung-up" on using "nothing but the best ingredients" Papa John's has already bought up all of the best ingredients...LOL. Like many of us here I like to "fiddle" with the ingredients and procedures....we're not making rocket fuel or nitroglycerin, just good food, and it always seems to taste a little better after I've played with it a bit. :chef:

[Re: What's your take on recipes? 2543](#)

I'm not quite sure what you are asking but the temperature of the dough will have a major impact upon how much the dough rises/ferments during any relaxation period. The warmer the dough the faster it will rise/ferment and the cooler it is the slower it will rise/ferment. This is why it is so important to control the finished (mixed) dough temperature to some pre-determined target temperature and then strive to hit or come reasonably close to that temperature with each dough.

[Re: Is it necessary to rest the dough?2544](#)

While defatted soy flour contains roughly 51% protein it is a non gluten forming protein so it really doesn't benefit flour in any way. Soy flour typically has 100% absorption, meaning that for each 1% soy flour added you need to increase the dough absorption by 1%. The main reason for adding soy flour to a dough is to provide a level of improved nutrition to the baked product. A lot of the flour sent overseas through the AID Program is fortified with up to 30% soy flour. In the commercial baking industry defatted soy flour is commonly used as a milk substitute in various pan breads and rolls/buns. It is also used in yeast raised donut mix formulations to adjust the absorption of the mix.

[Re: Soy Flour2545](#)

QJ is way ahead of me :).

What is the total weight of your "bulk" dough and what is the temperature of the dough?

[Re: work flow for long cold ferments](#)**2546**

I'm not overly fond of wrapping in plastic wrap/stretch wrap as I find that the dough has a greater tendency to stick to it than it does a plastic food bag, just my observation. Additionally, when handled correctly, the food bags can be reused any number of times before discarding them.

Placing the dough balls that have been plastic wrapped into a container only makes sense if you place it into the container and cover it after the dough has been well chilled outside of the container for at least 3 to 4-hours. Otherwise you're more likely than not to be trapping heat in the dough ball(s) which can result in an inconsistent rate of fermentation among your dough balls. Additionally, wrapping the dough balls in plastic wrap makes it difficult, even for me, to ascertain the quality of the dough as it pertains to the amount of fermentation it has received. The only observation I've been able to make regarding fermentation with plastic (stretch wrap) dough balls is that when they might be over proofed the plastic wrap will be stretched tighter than a drum and the dough will look like it is ready to tear through or pop the plastic membrane at any minute.

[Re: Storing Premade Dough Balls](#)**.2547**

Mike;

You're probably going to be ahead by storing them in the fridge. With a little luck you should be able to hold them up to three days or so, and if they begin looking over fermented just re-ball, lightly oil and place into individual plastic bags (food saver bags, not Zip-Lock), twist the open end to form a pony tail and tuck it under the dough ball as you place it into the fridge and you should be able to get a few more days from it.

[Re: Storing Premade Dough Balls](#)**.2548**

The best way to slack-out frozen dough balls is to lightly oil them while frozen and then place them into plastic food bags, twist the open end into a pony tail and tuck under the dough ball as you place it into the fridge, allow to thaw at least over night, then remove from fridge and allow to temper to 50 to 60F before opening. My favorite way though is to remove the dough from the fridge allowing it to warm to 60F and then placing it back into the fridge for use later in the day or better yet, on the following day, just remember to allow the dough to temper to 50 to 60F prior to opening.

[Re: UPDATED on Frozen Dough Balls](#)**2549**

The question begging to be asked is: What is the speed/r.p.m. of the spiral mixing arm?

[Re: what dough mixer!](#)**2550**

Dry milk solids, unless they are specifically labeled as "bakery grade" are low heat treatment meaning that it has not had the whey protein denatured so it will still need to be scalded prior to use or it can have a reducing (softening) effect upon the dough. Bakery grade milk solids have been exposed to "high" heat treatment so the scalding process is not required. Along the same lines, any low heat dry milk solids can also be used for making cheese but high heat cannot. This is why back when the CCC (Commodity Credit Corporation) had all that dry milk powder that was bought through the dairy subsidy program in government storage it was specified that it be low heat treatment which allowed the schools to draw upon the stocks of CCC dry milk and trade it to dairies in exchange for cartons of milk. The traded dry milk solids were then used in cheese production by the dairies. I had a project with

the CCC where I was traveling to schools and universities across the U.S. for two years showing them how to utilize maximum amounts of dry milk solids in baked goods. The scalding of the milk is only required in yeast leavened products, any type of milk or milk solids can be used in chemically leavened products without the need to scald.

[Re: Milk in dough 2551](#)

Julius;

For each 1% (bakers percent based on flour weight) of vital wheat gluten (VWG) that you add you will increase the protein content of the flour by 0.6%. If your existing flour has 10% protein content and you want to increase it to 14% (like All Trumps flour commonly used in N.Y.) you will need to add 4% additional protein so $4 \div 0.6 = 6.6\%$ VWG to be added. For each 1% VWG added be sure to increase the dough absorption by 1.8 times the weight of the VWG added.

NOTE: Be sure to dry blend the VWG into the flour before adding any liquids.

[Re: Adding gluten to low-protein flour? 2552](#)

I wrote an entire article on "the dreaded gum line" for PMQ Magazine some time back, maybe you can find it in their archives. There are MANY different things that can cause the gum line both singularly and in combination so it's impossible to immediately put a finger on the cause but maybe we can work through it.

Can you send me a picture of the pan you're baking the pizzas in? Also, what is the crown height (difference between the deck surface and inside top) of your oven?

[Re: Gum line issues 2553](#)

This should work for you;

Open skins in your normal manner, place onto pizza screens and refrigerate thoroughly, apply a LIGHT application of oil to the top of the pizza skin followed by application of the chilled sauce, place back into the fridge until needed (assuming 2 to 3-hours). Note: If you place a piece of parchment paper under each skin as you place it on the screen you can dress the skins and peel them (just as you are presently doing) into the oven in a timely manner without disrupting the dressed skin. As one pizza is baking the next one can be dressed and ready to go into the oven as soon as the baked pizza is removed.....assuming you can maintain temperature of the deck when baking back to back.

You can fully dress the pizzas in this manner too but in that case I'd recommend leaving them out to warm slightly (15-minutes?) as part of the staging of the pizzas prior to baking.

[Re: Prepping Pizzas in Advance for Party 2554](#)

Conditions in a dough or liquid ferment are not correct for reproduction as there is a deficiency of oxygen.

[Re: Fresh Yeast + Starter? 2555](#)

Can you provide any pictures? Top, bottom and cut edge would be helpful. Are the pizzas pre-baked and just reheated for serving or are they baked to the order as most pizzas are? TMI can also be a good thing when you're trying to figure out how somebody is doing something.

[Re: Crunchy crouton like pan pizza\(grandma pie\) 2556](#)

Your sourdough starter is comprised of both wild yeasts as well as lactic acid forming bacteria. The yeast doesn't multiply, but the bacteria, like other bacteria freely multiply and that is what you are seeing.

[Re: Fresh Yeast + Starter?2557](#)

The actual number of yeast cells does not increase substantially, instead what happens is that daughter cells mature as do budded cells but further budding does not occur unless significant amounts of oxygen and nutrient are introduced into the yeast slurry and held under strict pH and temperature conditions, this is how yeast is cultivated by the major manufacturers. If yeast cells were to multiply during fermentation we would have run away fermentation at the slightest provocation. I'm sure you can research how bakers yeast is made on the Internet to get more information and if anyone has the Pyler books (Baking Science and Technology/E.J. Pyler) I believe it's covered in there too.

[Re: Fresh Yeast + Starter?2558](#)

From a technical standpoint, yes, but from a practical application, no. The time gained wouldn't be all that great and there would be a fear of reducing the yeast to a level where it cannot produce sufficient leavening power to provide the desired oven spring which opens a Pandora's Box of good things to happen such as development of a gum line, tough, chewy crust, lack of crispiness, sometimes even getting the bottom to color up properly can result when the yeast is reduced too much. I see this quite frequently at pizzerias where they don't cross-stack or don't cross-stack long enough and the dough blows so they reduce the yeast to address the blown dough issue and end up with a plethora of new issues to contend with.

[Re: Warming up the dough - Why?2559](#)

So what you have there is a brew. It's common to not include the flour in the brew as part of your 100% dough flour as it is pretty well degraded due to all that fermentation.

Since yeast does not multiply during fermentation you will have the same amount after the fermentation period as you added to the brew when you set it, since you are adding only 75% of the brew you are getting only about 75% of the yeast that you added (0.36×75 press the "%" key and read 0.27-gram). So $0.27 \div 453 \times 100 = 0.0596\%$ yeast being provided by the brew (assuming 100% yeast survival). Considering that a typical pizza dough formulation will call for something on the order of 0.5 to 1% CY, I think you would be safe by just adding 0.5 to 1% CY with or without the addition of the brew, however, if the brew is deleted you will need to add the water contained in the brew to the dough formula and your dough management procedure will need to include sufficient fermentation time to condition the dough and develop flavor for the finished crust.

[Re: Fresh Yeast + Starter?2560](#)

One piece is still missing: How long do you ferment the poolish for and what is the temperature?

[Re: Fresh Yeast + Starter?2561](#)

It sounds like you might be making a brew but it's impossible to say without knowing how much water was used, how much yeast was added and how much flour was incorporated, then I would need to know your actual dough formula including how much of the "brew" you usually add to make a dough.

What type of yeast are you getting from your local bakery? From the description it (directions) it sounds like ADY or IDY. Most bakeries use fresh yeast/compressed yeast/wet yeast but the directions you provided clearly calls for some form of dry yeast.

[Re: Fresh Yeast + Starter?2562](#)

It might help a bit with the handling.

[Re: Does hydration change during fermentation?2563](#)

Matt;

That certainly sounds like your dough might be getting too gassy due to allowing it to warm up too much. Been there, done that too with the bubbles in the dough. As the bubbles form they displace dough so when you pop them there is little or no dough under them which results in the thin spots. I normally just treat it like a hole in the dough, pull a piece of surrounding dough over the thin spot or hole and press it down to lock it in place and hope for the best.

[Re: Warming up the dough - Why?2564](#)

My personal experience with Caputo flours is that they do not have a lot of tolerance to long fermentation times. I've found that the doughs made with Caputo were generally getting too soft to handle after 36-hours of total fermentation time (in the cooler), and seemed to be at their best after 24-hours.

Specific to your question, both water/dough absorption and fermentation have a significant impact upon the dough viscosity so a dough that is becoming too soft and sticky "might" benefit from the use of a lower dough absorption but if the stickiness is due to breakdown of protein and hydrolyzing of starch into sugars there will be nothing that can be done to alleviate the stickiness.

[Re: Does hydration change during fermentation?2565](#)

The greatest downside to letting the dough/dough balls rest at room temperature before placing them into the fridge is that during those 20-minutes the dough is beginning to ferment causing the dough density to change (become less dense) and become a better insulator as it does so. This in turn magnifies the effect of the finished dough temperature as it impacts the rate of fermentation, this is not a problem if your finished dough temperature is always "spot-on" but if you're like me you have those days when when you can only scratch your head and wonder how you ended up with the finished dough temperature indicated on the thermometer as it's not even close to target, this is when the real fun begins as the entire fermentation cart has been upset and you will now be forced into making a judgement call as to when the dough is ready to use and sometimes you win and well.....sometimes you don't. All of this can be avoided or at least minimized by taking the dough straight to the fridge as soon as possible after mixing and balling.

[Re: Dough troubleshooting2566](#)

If the "starter" is made using domestic yeast it is commonly referred to as a liquid ferment or brew. If there is sufficient flour present to give it a dough like consistency it is referred to as a "sponge". Essentially all white pan bread sold in the U.S. through the chain stores (supermarkets) is made from one of these two ferment systems. Typically the ferment provides about 50% of the required amount of yeast to leaven the dough with the rest of the yeast being added to the dough (commonly referred to as a "yeast spike"). The liquid ferment/brew/sponge main purpose is to condition a portion of the flour and to provide flavor for the finished product, the longer the fermentation time the more "fermentation" flavor will result. Without knowledge of your entire process I cannot say if the formula might need to be changed if you leave the yeast spike out but try it to see what you get, if you want more oven spring you can always add a small amount back as a spike.

[Re: Fresh Yeast + Starter?2567](#)

If you delete the domestic yeast from your starter then you will need to adjust your procedure to accommodate the leavening from your starter....some might say that you'll be making the dough by a sourdough process.

[Re: Fresh Yeast + Starter?2568](#)

E-300 appears to be what we call a "cocktail" ingredient comprised of ascorbic acid and amylase enzyme. You will see this here in the U.S. too. Puratos Company is a big supplier of these "cocktail" ingredients.

[Re: Malt + amylase in flour... Why ?2569](#)

Not really, I guess if you are talking about just a dough ball then doubling in size might be considered a good target, but in pizza production where we can go through a bulk fermentation period of a day or more and then scale and ball and give RF or CF to achieve final conditioning of the dough for opening into skins. As you can see, in this case there is a lot more fermentation than what we typically think of for bread (artisan breads excluded). The only dough test that applies to both bread and pizza doughs is the finger indentation test where a finger is pushed into the dough to the first joint and removed, if the dough doesn't do anything it is not ready for opening but if it recedes slightly it's ready for opening, if it collapses it's over fermented for bread but in most cases it will still work for making great pizzas. This is why we see so many different dough management procedures being used for making pizza with amount of total fermentation all over the board while with bread (think pan breads) you're limited to following some pretty common and basic guidelines for fermentation.

[Re: Question on cold fermentation and doubled rise2570](#)

Scaling error is the only thing that comes to mind. I'm not familiar with the specific starter so I can't comment on how using less of it might impact the dough and finished crust and it would make a difference if the flour or water were mis-scaled so it's impossible to say.

[Re: Tony's Poolish & Tiga Recipe's not producing the proper weight starter??2571](#)

Doubling of the dough volume is about right for bread but pizza technology is different from bread technology as the dough doesn't need to expand to nearly the volume that it does when making bread, this is why we can ferment the dough for extended periods of time for flavor development. The difference between cold fermenting and fermenting at room temperature is primarily in the type of flavor developed aside from any convenience factors.

[Re: Question on cold fermentation and doubled rise2572](#)

That first dough ball appears to have been rounded twice back to back which is why it has a rough/lumpy appearance. In a case like that where you find the second dough ball weights more than the one already rounded (balled) the correct thing to do is to just cut a piece off of the heavier dough ball and slip it under the lighter weight dough ball, then forget about it. The piece that you added will become as one with the rest of the dough ball.

[Re: One dough ball lumpy texture, the other smooth? 2573](#)

I should also mention that the dough balls appear to have been placed a bit too close together for your dough management procedure, it appears that only four dough balls would provide a better placement in your boxes.

[Re: PLEASE HELP: Issue getting dough out of boxes2574](#)

First of all, you only want to allow the dough balls to warm to 55 to 60F before using them, secondly, the second picture provided shows the dough balls just "kissing" so they should not be too difficult to remove using the correct tool. If you go to the WRH web site <www.wrh.net> and go into their pizza products and click on their scrapers you will see their scraper Model DS-2 which works very well in tight spaces, I have found that the DS-1 is a little too big for use in removing the dough balls from most boxes but it works well on the bench.

[Re: PLEASE HELP: Issue getting dough out of boxes?2575](#)

In all probability you don't have a reverse spiral dough arm for your mixer, instead, what it sounds like you might have is just a plain old "J" hook and it is a very common thing for the dough to climb up on the hook and just go for a free ride on the hook as you have described. We have discussed the reverse spiral and "J" hook in detail previously, you might want to take a stroll through the archives to find a few of these discussions, or if you want, just post a picture of your existing hook and we can make an immediate determination as to whether it's a reverse spiral or "J" hook.

[Re: How Much Protein per 100gr for High Hydration Dough?2576](#)

In most instances the domestic yeast will quickly become the dominant microflora and provide what we know as "normal" yeast fermentation however you can still have some of the residual flavor components of the starter to provide an additional dimension of flavor.

[Re: Fresh Yeast + Starter?2577](#)

Frenchy2000;

I still stand by my last post, begin with 100% Manitoba and begin introducing the Caputo in 25% replacement increments, it'll be a journey of learning and there will be some good pizza to be had along the way. :)

[Re: How Much Protein per 100gr for High Hydration Dough?2578](#)

If you wait too long and allow the dough to warm up too much it can become difficult to open, this is especially true if you have a high absorption dough, also the dough will become more gassy, those gas bubbles will begin to expand almost immediately upon placing the pizza in the oven resulting in more oven spring which we can live with at home but in a pizzeria it will make the pizza look different or if they are being baked in any kind of a conveyor oven it can dramatically impact how the pizza is baked....neither of these are favorable in the eyes of the consumer as it makes the pizza "different" be it good or bad. In a commercial setting we all know that quality is not necessarily attribute #1 (let's see a show of hands from all who agree). Operators like to think that it is but the real #1 is product consistency, if the product isn't consistent it don't make no matter how good the pizza is. We like to refer to this as the McDonalds philosophy, not the best burger in the world, but you ALWAYS know what you're going to get.

[Re: Warming up the dough - Why?2579](#)

When baking pizzas in a pan bubbles are much fewer and further between than when the pizza is baked right on the deck at those lower temperatures. Next time try baking the pizza directly on the stone or on a piece of parchment paper placed directly on the stone.

[Re: BUBBLY CRUST WANTED?2580](#)

DustinA:

This is due to the colder dough being slower to set/gelatinize while allowing more time for the yeast to generate leavening gas as well as more time for water vapor to turn into steam all of which contribute to what we refer to as the pita effect, where the bubbles become so large so as to make the crust look like a pita. When the dough is warmer the dough reaches the generalization point/temperature (about 140F) more quickly thus locking up the structure before it can be expanded into those large bubbles.

[Re: Warming up the dough - Why?2581](#)

JVP123;

I'm afraid that a cold dough will bubble excessively and possibly turn into a pita, but if one were to dock the skin well this might control the bubbling and possibly give something closer to the desired result....just to clarify, we are talking about surface "bubbling" not achieving an open, porous crumb structure.

We also know from work that we did on eliminating bubbling that fermentation plays a big role in bubbling. When a dough is made with less than 2.5-hours total fermentation time bubbling is prevalent and it diminishes as fermentation time is increased so if the dough is freshly made and fermented at room temperature for, let's say 1.5 or 2-hours, (mix, immediately ball, ferment balls for 2-hours at room temperature and open into skins for immediate use) this might also work, again docking might be necessary to control bubbling. Make sure to use a proper dough docker with flat points on the docking wheel.

[Re: BUBBLY CRUST WANTED2582](#)

I like to use a middle to upper one third rack position as I'm looking for more heat to the top of the pizza than to the bottom (remember, it's already fully baked). I do not recommend placing the pizza directly on a stone or baking steel as this will generally cause the bottom to get over done, instead I like to use a screen and just place it directly on the oven rack.

[Re: Dough Formula for Heavy Topped Pizza2583](#)

The wheat varieties from which Caputo flours are produced tend to give soft and extensible doughs while the wheat varieties from which U.S. and Canadian flours are produced are selected to give doughs with a lot of strength. If its strength that you are looking for I don't think high absorption Caputo doughs are the way to go, instead, start out using 100% strong (Manitoba) flour and work your way up to 70% absorption, once you have that mastered begin introducing your Caputo flour (to replace the Manitoba flour) in 25% increments. I would also suggest dropping the absorption back to not more than 65% with each addition of Caputo flour and working back up from there.

[Re: How Much Protein per 100gr for High Hydration Dough?2584](#)

The dough balls look like they're ready to open in the last two pics.

[Re: Overfermented dough or not?2585](#)

Since you're a novice at opening the dough, try this, we developed the procedure to train novices in opening dough into skins with as little effort as possible in the shortest time possible. As you become proficient you will gravitate away from the rolling pin and begin opening the dough totally by hand.

Procedure: Your dough should be made with approximately 65% dough absorption with 48-hours cold fermentation under its belt.

Turn the dough ball out onto a floured surface and dust both sides of the dough, using a rolling pin carefully open the dough to within about 2-inches of the final

diameter you are targeting, then hand or bench stretch the dough to full diameter...done. If you want to see this done in a video go to my web site <doughdoctor.com> and watch my dough making video (Part-3) will contain the instructions on opening the dough ball into a skin.

[**Re: BUBBLY CRUST WANTED**](#)**2586**

Are you using an autolyse? If not, include it in your dough making process by placing the flour and water into a bowl, stir until the flour is whetted, cover and allow the flour to hydrate for a couple of hours, then add the remainder of ingredients and mix. If this work for you begin experimenting with shorter autolyse times until you find a time that works well with your flour...it could be as short as 30-minutes or as long as 2 to 3-hours. Also, remember that high absorption doughs will always be soft and somewhat sticky. Lightly oiling your hands will make handling much easier and using a little extra dusting flour helps too. A bench scraper will be a big asset in working the dough and lifting it up off the work surface.

There are a few very good videos here showing the working of high absorption doughs.

[**Re: How Much Protein per 100gr for High Hydration Dough?**](#)**2587**

Have you contacted Middleby-Marshall about the problem yet?

[**Re: middleby marshall ps636**](#)**2588**

Sounds like a tasty bread. The things I would do are as follows:

- 1) Make sure the yeast level is at about 8% or a bit more (assuming compressed yeast).
- 2) Add only 1/2 of the molasses (unsulfured) and 1/2 of the fat (personally, I'd be using butter (unsalted)).
- 3) Mix the dough to about the same point as you would a pizza dough (just until it comes smooth).
- 4) Add the remainder of the molasses and fat and mix (medium speed) to full gluten development.
- 5) Look for a finished dough temperature of 80 to not more than 85F.

Process as directed from there.

If you don't have a process try this:

- 1) Scale and ball.
- 2) Oil the dough balls and place into individual mixing bowls that have been lightly oiled as well.
- 3) Drape with a sheet of light weight plastic to prevent drying and allow to ferment at room temperature for 2.5-hours.
- 4) Turn the dough out of the bowl onto a lightly floured surface and using a rolling pin form into a rectangle as long as your loaf pan is long (you want the dough to be about 1/4 to 1/3-inch thick).
- 5) Roll the dough into a log and crimp the seam to prevent unwinding, place into a greased pan and proof in a warm (95 to 100F) area until the dough rises about 1/2-inch above the top edge of the pan (a 1# loaf pan will require 18-ounces of dough). You can also proof the dough at room temperature, it will just take longer).
- 6) Bake at 425F for about 22-minutes. The loaf will have a very dark color. NOTE: Depan the bread immediately upon removal from the oven.

Alternative Method:

- 4) Turn the dough out of the bowl onto a floured surface and knead the dough for a few seconds, form back into a ball and place back into the lightly oiled bowl.
- 5) Allow the dough to proof in the bowl for about 70-minutes.

- 6) Carefully turn the dough out of the bowl onto a greased baking sheet, allow the dough to ferment for an additional 15-minutes at room temperature uncovered.
- 7) Carefully dock the dough by cutting a cross-hatch (#) into the top of the dough using a razor blade (you want this to cover the entire top).
- 8) Give the dough a very light misting of water and bake at 400F until done.

Note: Be sure to use ONLY oil where stated. For pan grease use regular Crisco.

I like to brush the top of the still hot bread with melted butter and drape with a clean towel and allow to cool on a cooling rack.

[**Re: bread question for Tom2589**](#)

Explanation:

When using a rolling pin you forcibly move air bubbles already existing in the dough around causing them to collapse (much like rolling out a piece of bubble wrap) which in turn causes many of the cells/bubbles to coalesce forming larger bubbles (they may not always be seen but they're there) and when heated in the oven those larger bubbles expand with much greater force than many small cells/bubbles would, causing them to coalesce even more which results in what you are most likely seeing. The use of a commercial dough sheeter/roller doesn't exhibit this characteristic as the dough is sheeted completely with each pass through the sheeting rolls resulting in pretty efficient de-gassing of the dough. One thing you might experiment with is using your rolling pin to open the dough to within about 2-inches (50-mm) of the desired finished diameter and then finishing the opening process by hand. When using the rolling pin in this manner the dough is still relatively thick so the coalescing of cells is not an issue and, as an asset benefit, you end up getting a much more uniform thickness across the entire diameter of the skin and finished crust. In short, it helps to address the problem of getting an overly thin center in the dough skin, a common problem experienced by most novices and some "old salts" too.

[**Re: The difference of a rolling pin and hand shaping 2590**](#)

Here's a little trick I used many years ago to increase the amount of garlic in the dough (as opposed to added to the finished/baked product), you will need to use dried minced garlic, blend it into some oil, the idea is for the garlic to absorb oil which will not be displaced by the water, this reduces the leaching of the garlic into the dough so you don't get as much dough softening from the garlic as you otherwise would, and the oil will help to retain more of the volatile compounds from the garlic thus creating a slightly more intense flavor in the baked crust.

[**Re: mixing flavor into dough 2591**](#)

I am a refugee from The American Institute of Baking (AIB) where I was employed for 50-years until my retirement 5-years ago. I ran the Experimental Baking Group for a good deal of that time and provided consulting services to the food industry world wide for over 20-years.

I developed the entire pizza program for AIB and authored a number of AIB Technical Bulletins on pizza related topics over the years. As a means of disseminating the knowledge we were learning about pizza from our research I developed the AIB Practical Pizza Seminar which I wrote the presentations for and lead the instruction for over 35-years (right up until my retirement 5-years ago). Yes, I'm implying that there "were" classes that you could sign up for. I don't know anything about the program anymore as I am no longer affiliated with AIB or its programs, but you might go to their web site at <www.aibonline.org> (unless

they've changed it) and look at their education seminar offerings. The class was usually scheduled in October. I have no idea if they still offer it or not and I have no idea of the quality of instruction or course content. When Jeff Zeak and I did the seminar it was second to none...a seminar is not successful that long by not being good, we even took it on the road and did regional seminars around the U.S. for a number of years.

[Re: Dough troubleshooting](#) **2592**

Actually, there was once a time in this country when flour was milled and shipped directly to the baker for immediate use but it was soon discovered that freshly milled flour wasn't the best for use in baking as it gave softer, stickier doughs requiring a lower dough absorption to handle decently. This was found to be due to a lack of oxidation in freshly milled flour so bakers began addressing this by storing flour near their ovens (a warm place/ heat = oxidation) for up to 30-days prior to use. Eventually flour millers began adding oxidation to the flour so it could be used within hours of milling without any problems associated with fresh aka green flour.

As for the difference in nutrient content of white v/s whole grain flour, enriched white flour is enriched to the same nutrient content as its whole-grain counterpart, the only difference being that the fiber (bran) portion is missing.

While white wheat varieties are all the rage today (they can be milled to a higher extraction rate than hard red wheat varieties while retaining a whiter color in the flour which means a greater flour yield per CWT (100#) of grain milled, hard red wheat varieties have historically been the most common wheat varieties milled for making breads, soft red and white wheat varieties are typically reserved for making low protein cake and pastry flours. The main type of wheat grown in Australia is hard white wheat while the main type of wheat grown in the U.S. and Canada is hard red wheat, with Canada growing mostly hard red spring wheat aka DNS (dark northern spring) while the U.S. grows HRW (hard red winter) wheat as well as DNS, HWW (hard white wheat) and soft white wheat varieties which are used for making lower protein flours as well as breakfast cereals.

[Re: Freshness of flour](#) **2593**

If you go to the PMQ web site <www.pmq.com> and go into the RECIPE BANK, use "dough" for your search word look for my home made pizza dough "recipe". I have used it for well over 30-years in all kinds of home pizza making applications and it works quite well. It'll get you started, then you can further refine it by getting a scale to weigh the ingredients which will allow you to modify the dough "formulation" to give you exactly what you are looking for and as you develop your expertise you will be able to modify the dough management procedure giving you even more control over the characteristics of the finished pizza.

[Re: Looking for a thin crust recipe](#) **2594**

Thanks for the concern guys! :)

I was in Minnesota at the cabin taking an extended vacation during which time I make it a habit to only occasionally monitor my e-mail and never go onto any of the boards in which I participate. Back for now but busy writing and consulting.

[Re: Is Tom ok??](#) **2595**

The most important temperature is that which is taken as soon as the dough is finished mixing (off the hook) as it sets the stage for all fermentation to follow (temperature is a major driver of fermentation as it has a significant impact upon the rate of fermentation). The rule that we follow in a pizzeria, and that which we

used to teach our students, is to get the dough completely processed (scaled, balled, boxed and into the cooler/cross-stacked) within a 20-minute window of time. This is assuming you have not over shot your targeted finished dough temperature. The reason for allowing this 20-minute window for processing the dough is that when we have a finished dough temperature within the 75 to 85F range and a total dough mixing time of 10-minutes or less, the yeast will typically exhibit a lag time of approximately 20-minutes, this is due to the yeast still acclimating to the environment of the dough as well as beginning to produce sugars to feed upon. The rate of fermentation is still very slow during this time so there is a minimal change in dough density during this 20-minute period which in turn is also important as dough density will have a significant influence upon the rate at which the dough is cooled. With all of that said, when we use a pre-ferment without any additional yeast being added to the dough the yeast is already actively feeding (fermenting) so that 20-minute window is cut in half to only 10-minutes.

[Re: Dough troubleshooting 2596](#)

Longer baking times can be employed with breads and rolls than can be used when making pizzas, additionally the type of sourdough starter and its strength (acidity) play a big part in the development of crust color.

[Re: Something Different Sourdough 2597](#)

That's the point I was making, even at temperatures of 750F we struggle to get much color from a true sourdough leavened product, specifically one that imparts a tart flavor to the finished product. I did not mean to infer that breads are baked at anything even remotely close to 750F.

[Re: Something Different Sourdough 2598](#)

The answer to #1 is....they don't. This is why sourdough breads and rolls are always so light in color unless they're baked at over 750F, and even that it's a struggle to get much color.

When you say "strengthen" please describe. Do you mean feed?

The type of yeast used can have an impact upon the finished crust flavor but flavor is a VERY COMPLEX thing and I have no idea of how volatile those aromas are. Your best bet would be to try it and see what happens, remember all yeasts, especially brewers yeasts do not ferment the same as bakers yeasts do so depending upon the strain you use it might not even perform in a dough system.

[Re: Something Different Sourdough 2599](#)

Neil;

In looking at the dough formulation I wish to comment on the following; The dough absorption does not change (it is unaffected by the weather or humidity).

Cultured/commercial yeast and active sourdough starter do not play well together, especially in a CF dough. The yeast completely takes over as the dominant microflora so the only thing you are getting from the addition of the sourdough starter is the acid content of the starter which you can get a lot more easily by just purchasing a dry, white sour. There are available from any bakery ingredient supplier such as Puratos Corp. or Watson Foods. I think Red Star/Lesaffre Yeast also now has one too. These are added to the dough as an ingredient at about 2% of the total flour weight and provide just what you have described flavor wise.

The acidity of the dough is what is inhibiting the bottom crust color development. If you want to get some color development you might experiment with adding some sweet dairy whey to the dough formulation, I would suggest a starting level of 3% and

work up from there. The whey contains roughly 71% lactose (milk sugar) which is the least sweet of all the sugars, only about 10% as sweet as sucrose, so it will not affect the crust flavor. No additional water will need to be added to the dough formulation when the dry whey is used.

Providing Consulting and Education Services to the Pizza Industry since 1967.

[Re: Something Different Sourdough](#)**2600**

Since you already have a working mixer, if it were me, I'd be holding out for a new spiral mixer.

[Re: Magic Mill DLX 2000 or wait for spiral?](#)**2601**

HBolte;

The conclusion that we came to confirmed what the baking industry has known for decades, humidity has no impact upon the immediate dough absorption when normal (relatively short) mixing times of 6 to 10-minutes are employed however, when long mixing times are employed, like when using a planetary mixer and mixing a dough for 20+ minutes at low speed, and in a low humidity environment (think El Centro, CA) the dough can dry out during the mixing process which usually requires that the dough absorption be increased by 2% to compensate for this but when we did a similar experiment in the Philippines (hot and very humid)we found that we did not need to reduce dough absorption for the same flour from that which we used at AIB (72F/50% R.H.). While I have not conducted these tests using a spiral mixer I would assume the results would be similar to that which we got using a planetary mixer. Where you do see a change though is when using a closed bowl mixer such as a commercial high capacity (800 to 2,000-pounds) dough mixer, in this case there is essentially no impact upon the dough due to exterior climatic conditions. This fact is well recognized in the commercial baking industry, the reason for this is due to controlled environment created within the closed mixing bowl. It should be noted though that the temperature and relative humidity (R.H.) can/will impact the moisture content of the flour over time which as expected will, in turn, affect the dough absorption when that flour is used.

[Re: Incorporate high oil content into dough](#)**2602**

You bet it will. Depending upon a number of factors including the strength of the flour and amount of oil in question in can result in a softer, more sticky or tacky dough than normal. A number of years ago we set about to find out what was at the root of people declaring that the weather was impacting the absorption properties of their flour. We made 10 doughs all at the same time using the process which was in common use at the time, put water and oil in the mixing bowl followed by the salt, sugar and yeast, agitate (this serves no purpose) and then add the flour and mix. What we got were about four different variations of the same dough out of the ten replicates. We found that the oil always floated to the top of the water where it was in direct contact with the flour, the oil would then begin to soak into the flour, since water cannot displace oil in the flour and gluten is only formed when the wheat proteins glutenin and gliadin are agitated in the presence of water, there was an unknown portion of the flour which was not capable of forming gluten, hence the unexplained variability in the dough which lead to Mother Nature being blamed the the variability. To make matters even worse bakers got into the habit of reducing the dough absorption when it was raining so now if a good portion of the flour did not form gluten the dough felt pretty normal but if only a small percentage of the flour became oil soaked more gluten was formed and the dough felt tighter/stiffer in the bowl so more water was added. In both of the above scenarios a less than stellar finished product was the end result. This all lead us to

look at developing a mixing method where the oil was omitted from the dough until the flour had a chance to fully, or nearly fully absorb the water, this is what we now call the delayed oil addition mixing method. It works so well that it is in common use in most pizzerias and essentially all, if not all, commissary operations where dough is made for a number of stores in a region. Mind you, this was all done using only 2% oil, as the oil percentage rises the situation gets a lot worse resulting in excessive dough variability.

[Re: Incorporate high oil content into dough](#)2603

More than likely it is due to the strength of your starter, it is not as active as the commercial yeast so the doughs are receiving less fermentation with your starter than they would receive using commercial yeast in the same period of time.

[Re: Dough stiffness when using starter v. commercial yeast](#)2604

Because a Roux is used to PREVENT gluten formation and we want to have gluten formation.

[Re: Incorporate high oil content into dough](#)2605

That's an impossible question to answer as all sourdough starters are different. Once you have made the starter and allowed it to settle down for a week or so of feeding you can begin using it. Start at 5% and work up in 5% increments from there. Remember, your starter will be 50% water so whatever amount of starter you use reduce the dough absorption by half of the amount.

[Re: sour dough starter](#)2606

My advice is to forget the kneading as you'll never achieve a homogeneous dough mass unless you put them into a mixer and remix back to a smooth dough consistency.

Why not just use the old dough to make some bread sticks?

Or, you could pin the dough out thin, cut into circles with a biscuit/cookie cutter and bake as mini-rounds, spread with some Ricotta cheese, add a basil leaf and a thin slice of ripe tomato and serve as an appetizer. Note: Be sure to dock them well and if they still pocket during baking just deflate immediately upon removal from the oven.

That way if they turn out decent you can surprise your friends but if they don't they'll never be any the wiser.

[Re: mixing 2 doughballs with different CF times](#)2607

I'd use it right from the can, that's how it was intended to be used. For me though, since I have a special affinity for garlic and fresh basil, I'd sauce the skin (right out of the can), add some sliced fresh garlic and then add a few leaves of fresh basil, add some fresh mozzarella and a little shredded or shaved Parmesan cheese and into the oven and get ready to enjoy a great pizza. :)

[Re: Got some 7-11 now what??](#)2608

Steve;

When we mix doughs with 20% or more shortening/butter/margarine we always mix the dough to essentially the full level of gluten development that we want for the product, the fat is then added and the dough mixed just enough to thoroughly incorporate the fat. This is necessary as the high levels of fat make gluten development almost impossible.

[Re: Incorporate high oil content into dough](#)2609

The spiral is the agitator and while mixing speed is highly subjective my recommendation is to mix the dough at low speed JUST until you don't see any dry (white) flour in the bowl, then begin pouring in the oil, after all of the oil has been added continue mixing at low speed for about one additional minute, then switch to the next higher speed and continue mixing until the dough begins to take on a smooth appearance. Every mixer is different and there are many variations of the spiral mixer but on average, I have found that for best oil incorporation (over 5% oil) you need to have enough dough in the bowl to allow the agitator (spiral) to remain in CONSTANT contact with the dough as the bowl rotates. If this doesn't happen the dough tends to just get all wadded up and tossed around by the spinning spiral without good mixing action. With most spiral mixers you will need to approach about 75% of the bowl capacity to achieve this effect.

Are you confusing the ability of a spiral mixer to effectively mix doughs as small as 25% of bowl capacity with the topic here of trying to effectively incorporate high levels of oil into the dough? If you try to incorporate high levels of oil into a dough using a spiral mixer with a too small dough size when you add the oil the dough will just begin flopping around in the bowl like a dying carp. With a planetary mixer the dough just balls up and gets pushed around, and around, and around, and around, etc., by the agitator and never gets any mixing action, at least not until you've had a chance to read at least half way through the novel War and Peace, it'll take a while.

[Re: Incorporate high oil content into dough](#) **2610**

The "Instant" part of IDY stands for instant hydrating (actually fast hydrating) and each one of those IDY cylinders is full of cracks and fissures which are what allows for the rapid hydration. If the IDY is put into cool water (below 95F) the water enters into the yeast and exerts a flushing effect on the yeast where the glutathione (the plasma material within the yeast cell) is flushed out before the yeast cells can expand to stop the flushing action (the warm water is what causes the yeast cells to swell) as a result the yeast cells are significantly damaged and fermentation is affected plus the glutathione exerts a reducing action, much like that of L-cysteine, on the dough which results in a softer, weaker, more extensible dough. As for oiling the dough balls this is important for two reasons, one is that it prevents the dough balls from drying out and developing a dry skin and the second is to allow for easier separation of the dough balls, even if they touch, they will be easier to separate in lightly oiled. Oiling of the dough balls is important if the dough is either cold fermented or fermented at room temperature in the box. Believe it or not, a skin will form on the dough faster during room temperature fermentation than when the dough is being fermented in the cooler.

[Re: Dough Improvements](#) **2611**

With a spiral mixer you should have the bowl filled to a capacity where there is a continuous strip of dough in the bottom of the dough, in other words the agitator should be in continuous contact with the dough, for most mixers this will probably mean something close to 75% of the stated bowl capacity.

[Re: Incorporate high oil content into dough](#) **2612**

And don't forget to do some research on the speed of the rollers (r.p.m.) that's an important aspect too, too fast and you shred the dough, to slow and the dough doesn't pull through the rolls as it should. Used dough sheeters are just too cheap to mess with. If you want to see something that is commercially made and somewhat similar to what you are describing check with National Manufacturing in Lincoln, Nebraska. They specialize in different types of small scale dough making

and testing equipment and amongst their toys is a dough sheeter/moulder that is used when making small scale "pup" loaves in a baking lab. I had two of them at AIB.

[Re: Making your own dough sheeter?2613](#)

Sure it's done but for the most part those days are gone, by about 15-years now. You need to be careful when adding onion and/or garlic to the dough as it will act as a reducing agent, making the dough softer and more extensible. There is a commercial product made from onion and garlic specifically for this application called Basic Natural from Cain Food Industries, Dallas, TX. The only difference is that in this application they are deodorized just like the Garlique Brand health supplement. Our research showed that this dough softening begins when the amount of dry onion and/or garlic exceed 0.15% of the total flour weight.

Little Lady Foods manufactures a type of crust referred to as a "dirty" crust. It's made using a blend of herbs, similar to the old PH herb crust. Cheese crusts can be made but they work better as a thick or pan style crust rather than a thin crust due to the propensity for burning. This is one reason why cheese dough has typically been reserved for bread sticks and rolls. Rather than using our regular cheese we found that using a white cheddar cheese powder at 5 to 10% of the flour weight made a much better product than when using wet cheese or grated/powdered cheese.

Old World Spices and Flavorings, K.C. Kansas used to have a really good herb blend that they made specifically for pizza crust applications.

[Re: mixing flavor into dough?2614](#)

Actually, there is a commercial product that is designed specifically for this application called Pizza Crisp, it looks like bread crumbs but it really isn't. We use it in some wholesale, high speed, high volume pizza manufacturing facilities in much the same manner as dusting flour is used. Where we use in most is on sheet and die cut lines where we are making thick crust pizzas which require post cutting/forming proofing of the formed dough pieces on a tiered/waterfall type final proofer. The Pizza Crisp is used rather than corn meal or flour as it provides for a better release from the proofer belts as the dough skins are transferred from one level to the next. FAILURE OF THE DOUGH TO PROPERLY RELEASE FROM ANY OF THE PROOFER BELTS IS NOT AN OPTION. If the dough were to stick to a proofer belt it would start a cascade event of dough pieces getting stuck to the conveyors and falling out of the proofer, in no time at all you can have 500 or more pounds of dough piled up in/on the proofer which will require an hour or more of line down time to clean-up, sanitize, and put back into production. In the mean time you have over 1,000-pounds of dough already on the line to contend with. This is not something one wants to contend with so the added cost of the Pizza Crisp is cheap insurance.

[Re: opening dough with breadcrumbs?2615](#)

Here are some places to begin.

1) DO NOT suspend IDY in cold water. Only suspend it in 95 to 100F water. In your case I'd put the cold water (60F) in the bowl first followed by all of the flour, add the salt and IDY right on top of the flour and begin mixing for at least 4-minutes at low speed, stop the mixer and allow the dough to rest for 15-minutes, begin mixing again just until the dough comes together and begins to smooth out, remove from the mixing bowl and begin your series of slap and folds.

2) I didn't see anything where you lightly oil the tops of the dough balls and left the dough box uncovered for at least 3-hours after placing it in the fridge. Failure to do

this contributes to erratic fermentation rate as well as sweating of the dough balls in the box which can result in an overly soft, weak and sticky dough condition.

3) Four hours is a long time to remove the dough prior to opening, instead, leave the dough balls out of the fridge, at ambient temperature (still covered) ONLY until the internal temperature of the dough balls reaches 55 to 60F, then you can begin opening the dough balls into skins for your pizzas.

[**Re: Dough Improvements**](#)**2616**

You're welcome Dustin, those great lookin' pizzas say it all! :chef:

[**Re: Dough troubleshooting**](#)**2617**

Steve;

Yes, garlic induced gelling would help to counter the issue but extreme care must be taken so as not to over thicken the sauce or it will be like tomato jelly on the finished pizza. When I was in Guatemala I was consulting for a company making their own sauce for their local pizza chain. At the commissary they were using a large industrial immersion blender to make their sauce and it bled out so bad they were adding a starch paste to it to help stabilize the sauce so it would retain its water, that worked BUT the resulting sauce was more like tomato leather after the pizza was baked. We resolved the problem by going over to grinding the tomatoes instead and it worked fine for them, problem solved.

But the challenges faced by the home pizza maker are not the same as those faced by pizzeria and commissary operators so if you're satisfied with that the immersion blender is doing for you continue using it, just be aware of its limitations.

[**Re: immersion blender?**](#)**2618**

The reason why there are so few answers to this question is because the true answer is....there isn't any. In the baking industry we depend upon the Farinograph or sometimes the Mixograph for the absorption of the flour but even this is just a standardized test for flour absorption as the baker ends up using what is called a Fariongraph factor for the "dough" absorption which is different from the flour absorption. One of the last projects I was working on before leaving AIB was with Dr. Rick Dempster on a concept for a fully automated bakery operation. Part of our work was to use NIR (near infrared) to control the mixing parameters of the dough. Since a commercial bakery pulls its flour from multiple flour silos with each silo containing flour from a different milling lot code and at some time another shipment of flour is put into each of the silos which combines with the remaining flour still in the silo for even greater variability in the flour being conveyed to each of the mixing stations within the bakery we had to develop a procedure where we could effectively determine the "actual dough absorption" through a real time measurement (about 15-seconds) so that the dough absorption at each mixer could be adjusted as necessary to accommodate the flour being delivered to the mixer for that specific dough. Rick was able to accomplish this using NIR at the flour weigh hopper located above each mixer. How accurately were we able to measure dough absorption based on this NIR measurement? Consistently well within 0.5% of the actual dough absorption as determined by a highly skilled baking technician. The ultimate test came when I challenged Rick to determine the actual dough absorption of a whole-wheat flour using his NIR measurement, after a full day at the bench doing multiple doughs and test bakes we had the answer, when this was presented to Rick his only question was "What took you so long?" His measurement gave a dough absorption that was again within 0.5% of what a skilled baking technician found AND it only took him 15-minutes, not a full day! We had been communicating with a number of the big pizza commissaries about installing the

equipment for a field test but the project was scrapped when we left AIB :(

[Re: Maximum absorption vs Whoops](#)**2619**

It's hard to be an arm chair quarter back but I'll take a SWAG at it. Is it possible the thicker stones are losing heat during baking but don't have sufficient time to recover their latent heat before the next pizza is placed on it so now you would see a lighter bottom bake on each subsequent pizza while the thinner stone without the ability to hold as much latent heat is literally just transferring heat directly from the burner beneath it, as a result there would be no recover time for the thinner stone. This is much the same principal that deck ovens used for baking bakery products (not pizza) work on. When you have a thicker stone you need a larger (more BTU) burner to enable maintaining the heat in the stone. When the bakery type deck ovens are used to bake pizzas they fail miserably when the oven is fully loaded with pizzas as the burner cannot maintain the temperature of the deck with a full load, but with just one or two pizzas in the oven it bakes reasonably well, like I said, just a guess.

[Re: Different thickness stones get the same result?](#)**2620**

Speaking of scales, if you Google Etekcity Digital Kitchen Scale you will find a bunch of low cost scales.

[Re: good deal on food scale](#)**2621**

The mixing speed appears to be OK but for whatever reason the dough is not developing sufficiently to even pull off of the bottom of the bowl.

Is the clearance between the agitator and bowl excessive? If the clearance is excessive the dough will do as seen in the video. Is the flour protein content too low? It should be at least 12%.

As for the finished dough temperature there are two things you can do to get it lower.

- 1) Replace 20% of the dough water with ice (either shaves or chipped ice, never ice cubes or tube ice).
- 2) Place a large pan under the mixing bowl and fill it with ice, water and salt. Place something under the brine water bowl to hold it up as close to the bowl as possible, this will help to keep the dough colder during mixing.

[Re: Frozen dough balls - finished dough temperature](#)**2622**

You don't see the tomatoes getting watery during the blending process but it's after the blending process when the that the syneresis becomes the issue, namely, when you sauce the pizza any water released from the sauce will go down into the dough where it contributes to the dreaded gum line and if, like me, you're in the habit of pre-saucing the skins during a multiple pizza bake, it just gets a whole lot worse. In a pizzeria you will easily know if the problem exists, the first of which is to observe your make people, if you see them stirring the sauce with the ladle, ask yourself why? The answer is because they saw separation of the sauce and they're just trying to recombine it. Again, if you're pre-prepping the skins for slam periods you're setting the stage for a gum line.

[Re: immersion blender](#)**2623**

When I have an amount that I cannot weigh on my scale I just double or triple the amount I need and then put it into say three ounces of water (95F) for IDY, I suspend the yeast in the water and then portion out 1-ounce of the water for my dough....presto! I just toss the rest out, call me wasteful if you want.

[Re: good deal on food scale](#)**2624**

Be sure to get a pic of the dough balls as you remove them from the fridge for tempering prior to opening.

[Re: Dough troubleshooting](#)**2625**

Not too bad at all :).

Experiment with your malt or sugar level if you want more color on the crust.

[Re: Dough too stretchy](#)**2626**

Scott;

I'm not aware of any other economical alternatives either. If you place a spoon full of your sauce onto a flat china plate and wait 15-minutes do you see water being released from the sauce?

[Re: immersion blender](#)**2627**

Place a suitably sized container on the scale platform, zero the scale, add the IDY to the measured amount that you want to use, remove from scale and use as directed.

[Re: good deal on food scale](#)**2628**

I use mine for a lot of chores around the kitchen even making myself an iced mixed drink occasionally but the one thing that I do not use it for is pureeing tomatoes unless I'm making tomato soup. It beats the tomatoes up too bad and ruptures many of the juice sacks contained in the tomato resulting in excessive syneresis of the sauce which ultimately leads to a "swamp" pizza.

[Re: immersion blender](#)**2629**

Yep, the bowl looks fine and that indeed is a reverse spiral dough arm.

To adjust the hook/agitator to bowl clearance on a Hobart planetary mixer there is a stainless steel cover on the pedestal just behind the bowl and below the bowl lifting arm, remove this cover and you will see a threaded rod with an adjusting nut. Don't forget to re-tighten the two locking nuts when you're finished.

[Re: Incorporate high oil content into dough](#)**2630**

I think where you may have gotten confused from other posts is where we suggest allowing the pizza to steam off for a short time before cutting and boxing the pizza for carry out or delivery. The last thing you want to include in the pizza box is steam. In the restaurants that I've been in where the pizza is served in the pan we remove the baked pizza from the pan and allow it to set on a cooling screen for a minute or so which allows it to steam off as well as set up a little, we then cut it using a rocker knife and place it back into the pan for serving. From a commercial (pizzeria) stand point this makes for additional work as the pans now need to be thoroughly washed, sanitized and dried before they can be put back into use again. When we serve the pizza without the pan we normally just wipe the hot pan out using a clean bar towel and either put it right back into service again or we place it into a container for the pans which are ready for use.

[Re: A little too much Moisture Issue](#)**2631**

I've never heard of any benefit to letting the pizza sit in the pan for several minutes after baking as this allows the pizza to sweat in the pan and since the pan is cooling the moisture condenses onto the pan sides and bottom Hummm? The next time you make your pizza try removing the pizza from the pan immediately after taking it out of the oven and placing it onto a wire cooling rack or pizza

screen to steam off and set-up a couple minutes before cutting.

[Re: A little too much Moisture Issue](#)**2632**

We do it all the time using as much as 16% oil addition to the dough. There are two tricks to doing this, one is to make sure you have a full size dough as this will ensure the best mixing action. The fact that you said the hook was just dragging the dough around in circles is an indication of a significantly under size dough for the bowl capacity/size. Second, you MUST be able to mix the dough at second or medium speed. One other thing to keep in mind is that it is absolutely critical that the oil be added at the correct stage of mixing. Put the water in the bowl first, add salt and sugar (no need to stir) followed by the flour and IDY, mix at low speed JUST UNTIL you don't see any dry flour in the bottom of the bowl, begin pouring the oil in over a 1-minute period of time and continue mixing for 1-minute at low speed after all of the oil has been added, then mix at second/medium speed just until the dough takes on a smooth appearance.

NOTE: If help to make sure the bowl to hook clearance is properly set before starting the dough mixing process. This is important for proper mixing of all doughs but it is doubly important with high oil content doughs. How to set the bowl to hook clearance? Place a nickel in the bottom center of the bowl, raise the bowl fully, if you can move the nickel you have excessive clearance, lower the bowl and adjust it just a turn or two into a higher position, continue this until the hook JUST contacts the nickel, remove the nickel, raise the bowl only partially, run the mixer at low speed, SLOWLY raise the bowl to its full up and locked position, do you hear at "tink, tink, tink"? if you do the hook is contacting the bowl and you will need to lower the bowl ever so slightly, if you don't, shut off the mixer, lower the bowl and CAREFULLY adjust the bowl a little higher and repeat the above process until you hear the "tinkling", then lower the bowl JUST until the sound goes away and you have the clearance set to minimum gap, you are now ready to begin mixing. Mind you, this is all based on the premise that you have a reverse spiral dough hook, if you have a "J" hook the first order of the day is to get a reverse spiral dough hook for your mixer and then begin the above process.

One other thing, look at the bottom of your mixing bowl, if it's dented, now is a good time to remove those dents. If it's severely dented you can not achieve the correct bowl to hook clearance.

[Re: Incorporate high oil content into dough](#)**2633**

I've never done a comparison as the dried sours are just too easy to use and they're readily available from most major bakery ingredient suppliers.

[Re: Sourdough starter worth it for pizza couple times a year?](#)**2634**

No problem at all in using IDY instead of ADY, just make sure to use the correct amount. You might want to refer to one of the charts for the recommended amount to use for your fermentation schedule.

[Re: Dough recipe for oven that gets up to around 650F \(PizzaQue Oven\)](#)**2635**

Dustin;

Try that first, then if that works for you see if you can begin incorporating some stretch & folds back into the process. Start with just one or two and increase the number gradually, and enjoy your pizzas along the way :chef:

Keep us posted on your progress.

[Re: Dough troubleshooting](#)**2636**

Huh?

Remove the dough ball from the box, place bottom side down onto a floured surface, flip the dough ball over so the top is now down and proceed to open the dough ball into a skin. If the dough has correct absorption, and has been fermented properly it should open easily, with the proper technique the dough can be opened having a relatively uniform thickness across the entire center section. You might go to my web site <www.doughdoctor.com> to get some tips from my video on making dough (part-2). Place the opened skin onto a wood prep peel using a little peel dust under the skin to facilitate transfer to the oven deck. For peel dust I like to use equal portions of flour, fine corn meal and semolina flour, but use whatever works best for you. Peel the dressed pizza int the oven (I place it just inside the oven door or slightly off to one side or the other) Leave the pizza set undisturbed for about 1-minute, if you try to move it too soon it will adhere to the deck (this is similar to searing a steak), as the dough bakes into a crust it will shrink and pull up slightly from around the edge allowing plenty of space for a turning/spinning peel to get under the crust. If the dough is too flat against the deck to get a peel under it your dough absorption or fermentation time are most likely too high/too long.

[Re: Problems with uniform dough discs](#)2637

And don't forget about surface tension too.

[Re: Flat squares instead of round balls](#)2638

One piece of critical information is missing...the finished dough temperature. You don't mention anything about cross-stacking or leaving the dough tray open for at least 3-hours in a home fridge as you indicated that you put the dough balls into a covered tray. What this all means is that in all probability the dough was over fermented to the point where the dough had become bucky, super elastic and difficult to open....sound familiar?

My recommendation is to use water at a measured 65F when making the dough, then measure the temperature again just prior to placing in the fridge (this is the critical finished dough temperature) as you will be looking for something in the 70 to 75F range. Now, when using dough boxes it is critical that the boxes/box be left uncovered for at least 3-hours when first placed in the fridge as this is going to allow the dough to cool properly and consistently, after that you can cover the box for the remainder of the CF period. As for leaving the dough out of the fridge for 3-hours prior to opening, this might be a bit excessive, instead, try leaving it out just long enough for the internal temperature of the dough balls to reach 60F before you begin opening them into skins.

Just for grins, try this: After adding the oil continue mixing the dough just to a point where is is taking on a smooth appearance, measure the temperature, IMMEDIATELY scale and ball the dough, place into the dough box, oil the top of each dough ball and place in the fridge uncovered for 3-hours, or until the internal temperature of the dough reaches 50F (whichever comes first), then cover and CF. After the CF period, remove the dough box from the fridge and allow to warm AT/AT room temperature until the internal dough ball temperature reaches 60F before you begin opening the dough balls into skins.

Keep us posted on your findings.

By the way, 0.5% IDY is, by most, considered to be pretty high for a 48-hours CF dough. I'd suggest reducing it to 0.250 to 0.375%. Additionally, the salt level is quite low at only 1%, I'd suggest increasing it to something between 1.75 and 2.25%. Both of these, the high yeast level and low salt level are significant contributors to excessive fermentation.

[Re: Dough troubleshooting](#)2639

You use 270-grams of dough for what size of pizza? 270-grams would be about right for a 12 to 13-inch diameter pizza.

If your starter is too strong the acidity will inhibit crust color development resulting in a lighter than desired finished crust but it will not result in raw dough in the crust after baking. Since your pizzas are lightly topped we can rule out excessive topping weight so we are left with too much dough weight for the size of pizza being made or the oven deck is not sufficiently hot. If the raw dough is in or close to the very center of the pizza there is a possibility that you are getting the dough too thin in the center section which would allow heat from the deck to pass through the dough and into the toppings (sauce) where the heat will be dissipated as steam without allowing the dough to reach sufficient temperature to fully bake it within the short baking time employed. Too much dough for a specific size pizza can require a longer baking time to allow the dough to fully bake but if the pizza is being baked as a larger size pizza employing the same dough weight it would be expected that the crust may not get fully baked. These issues are more prone to happen when short, hot bakes are used as opposed to longer bakes at a lower temperature.

[Re: Neapolitan Sourdough Pizza error](#)**2640**

Kneading and "stretch and fold" are both considered to be the same however for some there is indeed a difference. Kneading a dough the old fashion way calls for grasping an edge of the dough and pulling it back over the main body of dough and using the heel of the hand to drive the dough down into the main body of dough, the bowl is turned slightly and this is repeated for any length of time. Stretching and folding on the other hand is more like the way we incorporate roll-in fat into a Danish dough. The dough is elongated, the two lateral ends are folded back to the center line of the elongated dough piece, we then fold the dough over onto itself (like closing a book), in the production of Danish dough this is referred to as a 4-fold or a "book" fold. The dough piece is then rotated 90-degrees and the process repeated until the dough either develops a smooth appearance or it becomes too tight to continue stretching and folding in which case the dough is set aside and allowed to rest until it is sufficiently extensible to allow the stretching and folding to be continued. Is there a difference between the two types of "kneading"? There can be, using the stretch and fold method results in more of the dough being exposed to the air for a longer period of time which can result in a drier dough and if the humidity is sufficiently low it can also promote a more open porous crumb structure in the finished crust with proper handling of the dough.

[Re: Difference between "knead" and "stretch and fold"?](#)**2641**

Actually we don't look for great flavor/flavors in the dough but instead in the finished/baked product be it bread, pizza crust, etc. While enzymes do contribute to flavor development (in a round about way) they are not the major contributor. What do I mean by this? Enzymes present in yeast leavened doughs function by converting starch into sugars (amylase) and they also hydrolyze proteins (protease) which are then more easily denatured during the baking process which contributes to the flavor of the baked product, and then there is cellulase which breaks down cellulose into sugars much in the way the amylase works on the starch fraction of the flour but since there is so little cellulase present this is not a major contributor to any flavor development. In short, enzymes do not directly impact flavor, but they can do so by an indirect manner.

If you were to mix just flour and water together and allow it to rest for any period of time you would be making what a baker calls a "soaker". Soakers are extensively used to allow for complete hydration of whole-wheat and multi-grain type flours as

well as grains which are only partially milled so they are in pieces rather than a fine or coarse flour. All of these are difficult to completely hydrate as they require some time for this to happen, hence a soaker is used which allows the flour/grain mixture to be fully hydrated without any fermentation taking place. In commercial practice this is usually limited to something less than 4-hours at room temperature due to food safety concerns but in some cases, due to scheduling, the soaker must be made and allowed to hydrate for much longer than this, in those cases the soaker is stored under refrigeration until needed to make the dough.

Additionally, very little gluten is actually developed during any kind of a hydration period regardless of how long it is carried out for, the biochemical gluten development will not begin in earnest until the yeast is added.

When a soaker is used we just add it back to the mixer along with the rest of the ingredients and begin the mixing process, no special handling is required.

By the way, many people also like to refer to a soaker as an autolyze which is commonly used in artisan bread and pizza production.

When it comes to flavor development the oven takes first prize for being the most significant contributor which is followed by fermentation and all the good things which happen during and as a result of fermentation.

[Re: Enzymes and yeast](#)**2642**

Most of the dried sourdough "starters" are not starters at all, they are just dried sourdough that is inert as far as providing fermentation is concerned, this is why many call for the addition of yeast. Using these products will not adversely affect the yeast or gluten development but because they are acidic they will have a slight potential softening effect upon the dough as well as provide the "tang" you're looking for in the finished crust. Properly stored, (tightly sealed container in a cool place) these dried sourdough flavorings will last forever. We use these products commercially in many frozen pizzas as well as frozen pizza dough to add another dimension of flavor. In most cases the use level will be about 2%.

[Re: Sourdough starter worth it for pizza couple times a year?](#)**2643**

Yes,

- 1) The dough will be both sticky and slack (overly extensible).
- 2) The dough will not exhibit much, if any, oven spring during baking.

[Re: Frozen dough balls - finished dough temperature](#)**2644**

Let's just hope it's not a "cracker" crust pizza! ;D

[Re: A new pizza box design](#)**2645**

If you're lucky, really lucky, those dough balls will have a frozen shelf life of 10 to 15-days at the very best.

[Re: Frozen dough balls - finished dough temperature](#)**2646**

From the looks of the pizzas in your pictures I'm guessing that your dough weight might be too much for the size of pizza you're making (raw dough is a good indicator of this). If that doesn't address the issue you might try adding not more than 1% DIASTATIC malt to the dough for better crust color development during baking.

[Re: Neapolitan Sourdough Pizza error](#)**2647**

Amen! ^^^

[Re: Differences in preparing pizza dough](#)**2648**

Mo;

When par-baking those crusts be sure to bake at a lower temperature than you do for pizza, 400 to 450F is a good temperature. Also DO NOT bake right on the oven deck, instead, bake on a screen (the heat transfer is too fast on the deck and you will end up making pita every time). Bake just until the dough is COMPLETELY set.....no more. If the dough is not completely set you will see what appear to be oil spots on the crust as it cools, these are NOT oil spots, instead, they're areas where the dough was not completely baked and has collapsed (if you make a pizza from a crust like this those collapsed areas will become hard and "flinty". What is "flinty"? Think about eating a Chinet Plate.

When you see these characteristics the crust just needs to be baked a little longer. Immediately after baking invert the par-baked crusts onto a cooling rack. After thorough cooling par-baked crusts can be wrapped and stored at room temperature for up to 3-days. To use a par-baked crust first brush on a very thin coat of oil on the crust, then dress in the normal manner. If you plan on using the par-baked crust right away the approach is a little different, apply about 1/2 of the normal amount of sauce to the dough skin and then par-bake as directed above, As soon as the crust begins to show some color it is fully baked (you might need to experiment a little but in this case color is a pretty good indicator as to when the crust is fully baked). Remove the crust from the oven and place it on a cooling rack or pizza screen to cool for about 5-minutes, then apply the other 1/2 of the sauce and dress as desired, really heavily topped pizzas are best baked at 475 to 500F. Depending upon the amount of toppings used you might want to experiment baking both on the deck and on a pizza screen as the longer bake can result in excessive bottom crust color development when baked on the deck.

[**Re: Dough Formula for Heavy Topped Pizza**](#)**2649**

How are you determining that the dough is over fermented?

The only real way to make this determination is by observing the way the dough looks, handles and feels. Over fermented dough will collapse at the mere thought of being touched if it doesn't collapse on its own (this is not to be confused with the first full rise of a large bulk fermented dough which occurs several hours after the dough is mixed. When making BREAD the FFR is usually a pretty good indicator that roughly 75 to 80% of the full fermentation time for the dough has been achieved, but it has little significance in pizza dough since they receive considerably more total fermentation). The things to look for as indicators of an over fermented dough are as follows:

- 1) The dough feels lifeless with no elasticity.
- 2) The dough deflates easily during opening of the dough ball.
- 3) The dough will typically have a rough appearance to it.
- 4) It will feel sticky or tacky to the touch.
- 5) Little or no oven spring during baking.
- 6) The baked crust will have a light or mottled crust color.

[**Re: Additions to Your Dough**](#)**2650**

No, I would:

Put my ingredients in the mixing bowl and stir to combine, then turn out of the bowl onto a floured surface, lightly oil my hands and knead (stretch and fold the dough) until it becomes cohesive, lightly oil the bowl and place the dough back into it for 15 to 20-minutes, then turn the dough out of the bowl onto a floured work surface and begin kneading the dough again until the dough begins to look somewhat smooth. After that I cut it into desired weight pieces, ball, lightly oil, plastic bag and CF for 24 to 46-hours (occasionally longer). After the CF period,

remove from fridge, allow to warm AT room temperature until the INTERNAL temperature of the dough reaches 50 to 60F (anything in that temperature range will work well), then roll the bag down around the dough ball, invert the bag allowing the dough ball to fall onto a floured surface and begin opening the ball into a skin for immediate dressing and baking.

If I'm making a pan pizza, after the CF period and warming of the dough I open it to fit the pan, set the pan aside to proof for at least 30-minutes or more, then go back to it once again and carefully fit the dough to the pan so it completely fits the pan, I then set it aside to proof about 20-minutes more (occasionally longer) before dressing the proofed dough and baking the pizza.

[Re: How many times can I let dough warm-proof?2651](#)

When the dough gets too thin in the middle the heat isn't absorbed into the dough during baking, instead it just passes right on through the dough where it is dissipates as steam when it reaches the sauce and toppings which are roughly 90% water. In almost every case this overly thin center section will be excessively tough and chewy....maybe that's what you are finding objectionable?

[Re: Dough comes out too sticky at 60% hydration :\(2652](#)

Here are the proportions for a "typical" generic pizza crust in bakers percent.

Flour: 100% (typical bread type flour with 12 to 13% protein content)

Salt: 2%

Yeast: 0.3% IDY

Water: 62%

Sugar: 2% (variable/optional)

Oil: 2% (variable/optional)

[Re: Proportions 2653](#)

The "00" flour is not well suited to baking at the low temperature at which you are baking your pizza so I would suggest changing to a common bread type flour with about 13% protein content which has been malted. You should be able to find this flour in the baking section at just about any supermarket. Here is what I think might be a better dough formulation for you to begin with.

Flour: 100%.....1100-grams.

Salt: 2%.....22-grams.

Water: 63%.....693-grams. 70F/21.1C

Yeast:(ADY) 0.18%...2-grams. (be sure to hydrate/activate the ADY in a small portion of water at 100 to 105F/37.7 to 40.5C.

Target a finished dough temperature in the 70 to 75F/21.1 to 23.8C range.

You're going to be hard pressed to get much charring at your present baking temperature unless you include some sugar in the dough formula. I would suggest making the pizza first without any added sugar and then if you feel you need more crust color add 2% (22-grams) of sugar for the next pizza. You can then fine tune the sugar level as necessary.

[Re: Dough recipe for oven that gets up to around 650F \(PizzaQue Oven\)2654](#)

Toughness is highly subjective so it'll be hard to specifically address that attribute but the direction needed to achieve a crust that is crispy on the outside and soft on the inside is to bake the pizzas at a higher temperature and to include some oil in the dough formulation if it is not already being used. The amount I'd suggest for you to begin with is 3%, this can be olive oil or any type of vegetable oil you might have on hand (you can always experiment with using different oils if it works). The

crust itself really doesn't look too bad so I don't think the bubbling issue is in the dough but instead with the way the skin is being opened/formatted. It seems that you are leaving a lot of dough out on the edge of the skin which is resulting in that large edge crust where the bubble formation is. Getting that part of the crust thinner will also reduce the perceived toughness of the finished crust. Also, what is the total weight of the dough ball and the diameter of the skin you are opening it up to?

In the meantime, you might want to go to my web site <www.doughdoctor.com> and view Part 3 of my video on making pizza dough, in this segment we show how to open the dough so the center of the skin is not too thin nor is the rim too thick/heavy.

[Re: Dough comes out too sticky at 60% hydration :\(2655](#)

Pictures of the top and bottom of the pizza would help but to me it sounds like the deck is not heating or getting fully heated for whatever reason. Have you confirmed gas pressure? Correct hook-up? Have you contacted their support group yet?

[Re: Base of my pizza won't char2656](#)

For the way you're managing the dough I would suggest targeting a finished dough temperature of 70 to 75F, you can always change it if necessary later on. Use a dial/stem type thermometer to take the temperature of the dough both immediately after the mixing/kneading stage and again when you're ready to begin opening the dough balls into skins (here you're looking for a temperature between 50 and 60F). Pick a temperature and try to be consistent. Again, to measure the dough temperature at this point just insert the thermometer into the dough ball and record the temperature indicated.

When hydrating/activating ADY use a small amount of water at 100 to 105F (again, use the thermometer here too).

You don't say how you're CF the dough but my preference is to put the dough into a plastic bag (NOT A ZIP-LOCK BAG), lightly oil the dough ball, drop it into a plastic Food Bag (like a bread bag), twist the open end to form a pony tail and tuck the pony tail under the dough ball as you place it in the fridge. To remove the dough ball from the bag, just roll the bag down around the dough ball, invert the bag allowing the dough ball to fall out onto a floured surface. With this method there is no need to leave the dough container uncovered for several hours prior to putting the lid on it. Any problems with the dough sweating in the container are also eliminated when using the bags. As for a scale, there was just a number of posts on a pretty neat scale that might work well for you and the price point was around \$10.00....sorry guys, I didn't make a note of it or commit it to memory....feel free to jump in regarding this or any other scale.

[Re: Dough too stretchy2657](#)

Every bit of that, that's why I'm questioning the color represented in the photograph. If the crust is indeed that color it is most likely not thoroughly baked which would result in a "different" flavor as well as a more chewy mastication characteristic.

[Re: Dough comes out too sticky at 60% hydration :\(2658](#)

I have a question regarding the picture, is the crust really that light in color or is it just the lighting? What does the bottom of the crust like? Pizzas are baked from the bottom up so looking at the bottom of the crust might give a better idea of the bake the pizza is getting.

Also, you are saying dry but then you are saying that your jaws get tired of chewing (I know the feeling first hand), which would indicate toughness in the crust.

Keep hanging in there, you'll master it :chef:

[Re: Dough comes out too sticky at 60% hydration :\(2659](#)

It all depends upon the type of wheat that the all-purpose flour was milled from, if it was milled from a good quality hard red or white wheat variety you could get some of the characteristics of All Trumps flour from the ap flour through the addition of VWG BUT when supplementing flour of a lower protein content with VWG the resulting blend while having the same protein content as All Trumps (14% +/-) will always tend to produce a tougher, more elastic dough. The reason for this is because what you are supplementing with is all gluten forming protein while a portion of the 14+% protein in All Trumps is not gluten forming protein. Also, since the VWG is already fully developed gluten the doughs containing VWG usually exhibit a slightly tougher, more elastic characteristic.

[Re: Vital Wheat Gluten2660](#)

A couple of questions to ask:

- 1) What was the finished dough temperature (after kneading)?
- 2) Why so much ADY? 0.5% would have been plenty.
- 3) Did you hydrate/activate the ADY prior to addition to the dough? If so what was the water temperature?
- 4) Why leave the dough at room temperature for 7-hours prior to opening? The dough will handle much better for you if you just allow it to warm to 50 to 60F (internal temperature) prior to opening.

The condition which you described for the dough soon after kneading is completely normal as biochemical gluten development will do the gluten development for you as kneading is a pretty poor way to develop gluten.

[Re: Dough too stretchy2661](#)

I'd be looking at the one with 13% protein content (Cuoco) as my first choice.

[Re: Flour question for Detroit style pizza2662](#)

Dough formulation won't have a great impact upon the strength (resistance to collapse) with a par-baked crust, but here is a dough formula that might fit your needs:

Flour: 100% (strong bread type flour)

Salt: 1.75%

Sugar: 1.5%

Oil: 2%

IDY: 0.375%

Water: 62%

By using a dough ball weight of 12-ounces for a 12" pizza you will have a dough loading of 0.106-ounces (very close to what you asked for) per square inch of surface area.

[Re: Dough Formula for Heavy Topped Pizza2663](#)

How are you milling the tomatoes?

[Re: Watery tomato sauce2664](#)

JPB;

My opinion is that it's pure, unadulterated nonsense. They are partially right in that

the water can/will impact the flavor of beverages, we all know that, but from there on it's hogwash. The video tells it all. The system replicates the molecular structure of New York City water. Most of us know what the molecular structure of NYC water is, it comprised of two hydrogen molecules and one oxygen molecule, anything else is not water!

That's my story, and I'm stickin' to it! :-D

[Re: Watermarker?2665](#)

Just be careful to mind the water temperature, once you reach 140F you are in the enzyme deactivation temperature range and by 180F you essentially have non-diastatic malt syrup as all of the amylase will have been destroyed.

[Re: Ok to freeze low diastatic malt2666](#)

JKB;

Just don't hold the garlic butter over from one day to the next and you'll be fine. I usually prepare my garlic butter while the dough is proofing so it's rarely made more than 90-minutes prior to use. If you are just putting garlic butter onto a commercially made bread make the garlic butter about an hour, or so, prior to meal time then dispose of any remaining product (I never have any remaining product as it gets divied-up between all of the slices).

[Re: Flavored and Infused Oils2667](#)

Those large bubbles are due to the very short fermentation time you used. They will go away once you begin giving the dough normal fermentation. If you can, allow the dough CF for a little longer than 24-hours, I'd suggest going for 30-hours or a little more for your first pizza and then begin experimenting with increasing the CF time in 12-hour increments to find what works best for YOU under YOUR specific conditions. Once you've done this and you have developed your skills and confidence to a level where you are making good pizzas (this actually comes pretty quickly) you can begin experimenting with other aspects of your pizza. Be aware though that there are some potential ramifications to experimenting with pizza.....potential weight gain, and finding new friends weekly are but two of them :-D

And remember, when experimenting with pizza, even the mistakes will taste pretty good! :)

[Re: Dough comes out too sticky at 60% hydration :\(2668](#)

Malt Products Corporation is also a major supplier of malt to the industry

<www.maltproducts.com>

[Re: Ok to freeze low diastatic malt2669](#)

Mike;

If you go to the PMQ web site <www.pmq.com> and go into the RECIPE BANK, use "pizza" for your search word and look for my home made pizza dough "recipe". It might help you get started making pizzas. That alcohol aroma is a good thing....you only smell it in the dough. Alcohol is a byproduct of the fermentation process and it's part of the flavor development process vital to a good crust. Also, I DO NOT recommend using a glazed tile, instead, get an un-glazed tile (they're used on floors), or you can also go with a baking steel or a biscuit stone.

[Re: dough recipes2670](#)

My preference is 11-ounces (312-grams) but some like to use 10-ounces (284-grams), the heaviest I use is 12-ounces (340-grams).

[Re: dough ball size for 12 inch pizza](#)**2671**

They both provide sugar for the yeast to feed upon during fermentation with any residual sugars helping to promote crust color but if you use too much sugar the dough just ferments slowly, the crust tastes sweet and it will have excessive crust color. If you use too much diastatic malt the dough will become sticky with no way to correct it. With excessive diastatic malt the crust can develop a "malt" flavor, much like that of a malted milk ball (candy). If you have a flour with a high level of damaged starch sugar will have little or no impact upon the dough but diastatic malt, at just about any level, will essentially liquefy the dough within an hour or so of mixing.

[Re: diastatic malt vs sugar](#)**2672**

The biggest problem with malt powder is that it's dog gone hygroscopic. My advise is to repackage into smaller bags so you're not opening the large bag continually which will just lead to one large lump of malt powder. I DO NOT recommend freezing it, not that it'll hurt it but when cold meets warm condensation is formed which is what you DON'T want.

In summary:

3 to 5# bags (double bag).

store at room temperature.

Remove what you need and IMMEDIATELY reseal the bag.

[Re: Ok to freeze low diastatic malt](#)**2673**

I took this to mean that upon the second pass through the sheeter (we usually use two or three passes through the sheeter, turning the dough 90 degrees between passes) but if the dough is indeed being re-balled at any time just prior to sheeting the dough will tighten up and the sheeting rolls will end up destroying the dough as Yael has stated.

Treefetty can you please clarify this for us?

[Re: Why is my dough doing this?](#)**2674**

POD;

If your dough continues to be sticky even after weighing all of your ingredients here is something to try;

- 1) Mix the dough ingredients together as you have been.
- 2) Drape a damp towel or piece of plastic over the mixing bowl and allow the dough to ferment for 2-hours.
- 3) After the 2-hour fermentation period scrape the dough out of the bowl onto a floured surface.
- 4) Very lightly oil your hands and begin kneading the dough using a series of stretch and folds.
- 5) Continue the stretch and folds until the dough begins to look smooth.
- 6) Immediately scale into desired weight pieces and form into balls.
- 7) Lightly oil each dough ball and place into individual plastic bags (bread bags), twist the open end of the bag into a pony tail and tuck it under the dough ball.
- 8) Place dough balls into the fridge to CF (cold ferment) for 24 to 48-hours.
- 9) Remove dough balls from fridge and allow to warm AT room temperature for at least 1-hour.
- 10) Remove dough ball from bag by rolling the bag down around the dough ball and then inverting the bag allowing the dough ball to fall out of the bag onto a floured surface.
- 11) Begin opening the dough into a pizza skin.

12) Dress the skin and bake.

[Re: Dough comes out too sticky at 60% hydration :\(2675](#)

The reason why I asked is because a walk-in cooler performs differently than a reach-in when it comes to dough fermentation. The walk-in is going to be MUCH more efficient at cooling the dough so with all things equal you may find the dough lacking in fermentation when you begin using the walk-in cooler. To compensate for this we typically recommend increasing the finished dough temperature by 5F when going from a reach-in to a walk-in cooler.

[Re: Why is my dough doing this?2676](#)

You have nothing else to do? It seldom ever takes me more than 10-minutes and that includes scaling the ingredients and cleaning up (not much to clean-up).

[Re: Please tell me why?2677](#)

If you're going to bulk ferment it is always best to do so in a container which presents the smallest top surface like a tall cylindrical container. By immediately subdividing the dough into individual pieces and balling, then boxing and oiling the top of the dough balls then cross-stacking for 2 to 3-hours (time varies with the type of cooler and dough ball weight) then down-stacking and cold fermenting for a period of time (usually 2 to 3-days) you completely avoid the sweating issue and you get a much more consistently performing dough yielding more consistent quality pizzas which is the name of the game in commercial pizza production where failure or variability is not an option.

[Re: problem with large air bubbles/blisters in the cornice2678](#)

Welcome! You came to the right place. Just to bring us up to speed can you share with us what you have at hand for making Neo. pizzas? How will you mix the dough? Tell us about your oven. Do you have a specific flour in mind? Over here TMI (too much information) is seldom an issue. :)

[Re: Need Napolitan pizza at home2679](#)

I don't know your dough so this is just an educated SWAG.

While the dough was actively fermenting when you balled it I think the smaller dough balls (as opposed to bulk) will cool a little better, though not as well due to the gassy nature of the dough, so they will continue to ferment more than normal even while in the fridge. It's not the 1-hour extra time up front, it's the condition that it created that is problematic, (gassy dough is difficult/impossible to cool properly), so with this said, I think if you handle the dough as LITTLE as possible and open it carefully you will probably be OK. Take a look at the dough in the afternoon if you can, this will tell the story, if the dough balls have even a remote resemblance to normal all is good, but if they are flattening out/collapsing or blowing the news is not good, but even then a skilled pizza maker can do wonders to salvage a dinner party.

Good luck, let us know how the pizzas come out.

[Re: Advice- dough for tonight2680](#)

While flour strength and protein content are not always synonymous for the most part (at least in the U.S.) it is so for that reason I will say yes, as I pointed out in my initial response protein content/flour strength impacts the "potential" crispiness. This means that ultimately you can get a crispier crust from a higher protein content flour than a lower protein content flour, but to achieve maximum crust crispiness with any flour you must do your part to get that crispiness, that's the

challenge.

[Re: How to get crispier crust?2681](#)

Yael;

I'm going to pay you the same compliment a professor once paid to me.
"You're getting to be one smart cookie!" :).

[Re: Dough comes out too sticky at 60% hydration :\(2682](#)

The "sweating" of the dough might be what is causing the problem. When you put a large bulk dough in the cooler it really doesn't cool down very much due to the inefficiency of trying to cool a single large dough mass which is actually increasing in temperature with time due to heat of metabolism. The warm dough and the cold air in the cooler result in condensation forming on the dough. Since the condensation only forms where there is head space the idea is to eliminate any free head space. This is easily done by lightly oiling the top of the dough and then covering it with a sheet of plastic/polyethylene pressed tight to the surface of the dough. Try this and see if it addresses the problem.

[Re: problem with large air bubbles/blisters in the cornice2683](#)

Not including the flour that was used in the starter (that flour is pretty well shot), how much flour are you putting into the mixing bowl?

[Re: problem with large air bubbles/blisters in the cornice2684](#)

The dough should be dense when you're kneading it. In some cases I will knead the dough for a couple of minutes and then allow it to rest for 15 to 30-minutes (this is to allow for flour hydration) and then continue kneading it for a few more minutes. I never try to knead a dough to develop the gluten, just enough to get a somewhat smooth dough and then I let biochemical gluten development do the gluten development for me.

[Re: How many times can I let dough warm-proof?2685](#)

Where to begin?

Here goes.....

Dry yeast is hydrated/activated in water at between 95F (for IDY) and 100 to 105F (for ADY). Don't know where that 120F came from but it is TOO HOT.

The temperature of the remainder of the water (after a small portion has been used for hydration/activation of the yeast) is adjusted to whatever temperature is necessary to achieve the desired/targeted finished dough temperature (normally something between 75 and 85F).

Most tap water from a municipal supply is adjusted to a pH of 6.9 to 7.0, if you have sulfur water it will be more alkaline and need to be adjusted to 7.0 through humidification (vinegar or MCP/mono calcium phosphate).

Distilled water is not preferred to hard water (this has been discussed in these pages a number of times). The minerals in hard water are good for the dough and actually serve to help strengthen it.

The most economical way to measure water pH is through the use of pH test strips. These are available on-line as well as at most pharmacies and pool supply stores. When making no-time/emergency doughs 2% of the water is sometimes replaced with an equal amount of 50-grain strength white vinegar to help speed up the fermentation rate but this serves no practical purpose when not making no-time/short-time doughs. Adding baking soda to very acid water would indeed neutralize the acid BUT if there is any un-reacted soda it will serve to make the water alkaline which will, without question put the brakes on fermentation.

Are you having a water issue?

[Re: Safest PH level and temperature for water?2686](#)

Ted; There is a plethora of things which impact the crispiness of the crust. The protein content affects the potential crispiness of the finished crust. The main things that affect crispiness are:

Dough absorption: Higher is better (within reason)

Fermentation: Longer fermentation times promote more crispiness.

Baking: A longer, slower bake promotes more crispiness.

Hand forming the skin: Hand formed skins typically produce a crispier finished crust than those opened by machine or rolling pin (only applies to full diameter opening).

Less toppings is better: The fewer the toppings the easier it is to get a crispy crust.

Par-baked crusts: Par-baked crust will almost always give a crispier finished crust than one that is baked from raw dough.

[Re: How to get crispier crust?2687](#)

Additionally, how are you mixing the dough and what is your dough management procedure?

[Re: Dough comes out too sticky at 60% hydration :\(2688](#)

The answer to your question is : French Bread, Vienna Bread, Italian Bread, Bagels, Pretzels.

A typical formulation for pizza doughs would cover the formulation for all of the above. One year when we did our pizza seminar we had our students make pizza from commercially made frozen dough for each of these products to prove the point and the resulting pizzas were all very similar.

[Re: How does pizza dough differ from dough intended for rolls/sandwiches?2689](#)

Very carefully disect a few of the balls to see if somewhere within the ball you can find/see a small particle of your garlic. You might also do a "positive" test by simple making another sauce without the garlic to see if the balls develop in the sauce without the garlic, if they don't you've got both the answer and solution.

[Re: Is this that garlic-caused pectin gel that Tom Lehman has talked about?2690](#)

What is your total flour weight?

[Re: problem with large air bubbles/blisters in the cornice2691](#)

JKB;

That was my first thought too, they look like the grape tomatoes that I grew a couple years ago...about the same size too.

[Re: Is this that garlic-caused pectin gel that Tom Lehman has talked about?2692](#)

June;

Malt (powder or syrup/diastatic or non-diastatic) = sugar. In some dough formulations malt may provide a slightly different finished crust flavor than regular sugar but in my humble opinion this is more important in bread making than pizza making due to the toppings masking crust flavors. Take your pick, sugar or malt, or use both if you want but keep in mind that if you use both at 2% you have just increased your total sugar level to 4%, twice of what it was originally and you will get more crust browning, maybe a little inhibition of yeast activity (depending upon the yeast level) and possibly a little sweetness in the finished crust. If you are familiar with Papa Murphy's Pizza crust you know what 5% total sugar tastes like.

[Re: Need some input on how much IDY yeast is correct amount for a 24 hr CF](#)**2693**

Plan on placing the dough balls 2 to 2.5-inches apart which is a pretty standard spacing to allow for expansion of the dough balls. But do keep in mind that expansion of the dough balls is something that I cannot predict as it is influenced by a number of factors such as dough temperature, dough absorption, dough viscosity, amount of yeast used in the formulation, dough management procedure being employed, and how tightly the dough balls are rounded.

[Re: Dimensions for a wood proofing box?](#)**2694**

The size of your dough fermentation box will need to be based on the spacing of the shelf rails in the wine cooler. If it doesn't have shelf rails then we typically size the boxes to be 25mm narrower and 50mm shorter than the inside dimension of the cooler box. As for height I'd suggest something about 75mm in height.

[Re: Dimensions for a wood proofing box?](#)**2695**

Typically, the entire mass just thickens usually to the point where spreading the sauce becomes problematic unless lots of extra water is added to thin it back out again to spreading consistency. I've never seen anything like those little "jelly balls" form but if I had to take a guess it would be that within the core of each of those balls is a small piece of garlic....something to take a close look at.

[Re: Is this that garlic-caused pectin gel that Tom Lehman has talked about?](#)**2696**

OK, you've convinced me, I'll just admire them and dream of those great tasting steaks. Believe it or not, it wasn't too long ago when they were considered a nuisance, like deer in New Zealand (South Island). They taste good too! :drool:

[Re: water buffalo ribeyes!](#)**2697**

Jerry;

Easy one to answer, leave the lid off of the container for about 3-hours after placing it into the fridge then apply the lid and forget about the dough until you're ready to use it (keeps this way up to at least 3-days). This should address the wet dough and big bubbles. The wetness is due to condensation forming inside the container and the bubbles are due both to the wetness and the heat build-up in the dough due to covering it right away. This issue is exacerbated when you have a high finished dough temperature (above 85F). One good way to get around the problem is to use plastic "food" bags (not ZIP-LOCK bags). This has been discussed in detail fairly recently here.

[Re: Dough Mangement](#)**2698**

Thank you for the report. It looks like it would be a great little scale for anyone who doesn't have one or who is short on cash or storage space. It would be nice if we could post this to an equipment page for future reference.

[Re: good deal on food scale](#)**2699**

I've got a .375 Ruger that would put three of them in the freezer. :D

[Re: water buffalo ribeyes!](#)**2700**

What kind of cooler are you working with tight now, a reach-in cooler?

[Re: Why is my dough doing this?](#)**2701**

While on the topic, the second most common cause of the bubble that you're seeing is when baking the pizzas on a solid deck, especially a hot one. To test this theory

try placing a screen under the pan for the first half of the bake. What happens in this case is the dough is expanded too quickly resulting in coalescing of the gas cells in the dough which creates one large bubble which is trapped under the crust. Where we had no choice in reducing the baking temperature a screen can help by slowing the heat transfer to the bottom of the pizza or if you want to take a reformulation approach reducing the dough absorption can also help, in this case the amount will be variable depending upon what the present dough absorption and dough viscosity are but usually a 3 to 5% reduction helps.

[Re: detroit style in a convection?2702](#)

Just a few drops is all it takes, if you can see a shine on the inside of the container you have enough oil. Don't worry about extra oil, the pizzas coming out of the big box chains are made from dough balls that are brushed liberally with oil, it actually contributes to the crust color.

You pizzas look great!

[Re: Too much oil in dough ball container2703](#)

I had some of those when I was in Australia....very good indeed but as I remember the meat is a ruby red making the steaks look like they were taken from an animal that had been beat to death with a bat. But still very good!

[Re: water buffalo ribeyes!2704](#)

In our research we saw this bottom characteristic more often when the doughs were not sufficiently fermented so you might try giving a couple of your dough balls an extra day of fermentation to see if that is indeed the issue in your case. Let me know what you see. I see no reason why you couldn't do canned vegetables for catering as well as chicken and just about anything else in a Garland Air Deck oven, you might need to place some of these items on a double sheet pan and cover the pot/tray that they're being heated in (this will protect them from the airflow thus turning your oven into something more like a convection or "hot box" oven. My "partner in crime" Jeff Zeak used to work the XLT booth at Pizza Expo and make just about anything you could imagine in their air impingement ovens using just a regular pizza top and bottom finger profile. You might contact XLT Ovens in Wichita, KS and ask them about the different things that Jeff made in their ovens. I mention this because the air deck oven is just like any other air impingement oven except that it has a stationary grid for a deck as opposed to a moving conveyor which gives the operator the ability to bake items for whatever length of time they wish as the oven is operated/tended just like any other deck oven.

[Re: detroit style in a convection?2705](#)

Db1;

Thank you for clearing that up. We have tried and tried to make decent pizzas in those kinds of ovens but were never truly successful. Best to leave that oven to its intended purpose in my opinion.

[Re: detroit style in a convection?2706](#)

Doughball;

Everything has to be baked in a pan or on a disk or screen in the Garland Air Deck Oven. It is essentially an air impingement oven without a moving conveyor. Just to clarify: When you say "convection" do you really mean convection or do you mean air impingement? Huge difference between the two. If you mean "air impingement" then Shuboyje is absolutely correct in his response. I've worked in a number of pizzerias making Detroit style pizzas using air impingement ovens. If

you are not familiar with air impingement ovens I would HIGHLY encourage you to learn as much about their operation as possible before buying one. If buying new you can have the oven set up with a top and bottom finger profile specific to your SPECIFIC needs. XLT and EDGE both do a very good job of this.

[Re: detroit style in a convection?2707](#)

I've not tried it but from the specs it falls in the General Mills Remarkable to All Trumps range so it should work quite well for a N.Y. style of pizza.

[Re: Sam's Club Bread and Pizza Flour2708](#)

How big of an oven are we talking about here? If "big" is the answer how about a Garland Air Deck oven? No recovery time.

[Re: detroit style in a convection?2709](#)

Pizza Garage;

You and I are of the same mind! ^^^

Cold dough can even do that. Impossible to say which one is responsible without the details.

[Re: Why is my dough doing this?2710](#)

Brent;

It sounds like the dough is over fermented and has developed the "bucky" characteristics of an over fermented dough.

[Re: too elastic2711](#)

Without knowing what the pH and TTA of the dough and SD started were I can only take a SWAG. I'm guessing that the amount of SD added lowered the pH of the dough to a point which was more favorable for the fermentation progress which was why you observed what might have been more rapid fermentation. Also, remember that with more SD the dough typically shows more softening (mellowing) due to the affects of the acid on the gluten forming proteins and dough softening can easily mimic the effects of over fermentation because in a way they are very similar in that an over fermented dough is more acid too, in this case you're just adding the additional acid in the form of the SD starter. I don't know if that bucket holds water or not, like I said....it's just an educated SWAG.

[Re: Sourdough fermentation with hybrid dough..a question2712](#)

As pizza continues to morph we are seeing something of a trend for "free form" pizzas. The big box store chains will continue with the "cookie cutter" approach as it's somewhat necessary for portion control, and training, not to mention consistency of bake through a conveyor oven but for the independents with deck and stone hearth ovens we are beginning to break out of the round pizza mold. The most common departure appears to be an oval shaped pizza which still lends itself to cutting into relatively equal size pieces. I seldom ever strive for the perfectly shaped "round" pizza when I'm making pizza at home and I've not yet had a single person refuse it because it wasn't round, square or rectangular. :chef:

[Re: Flat squares instead of round balls2713](#)

It would help a lot to know your dough formulation as well as dough mixing and and dough management procedures. How you bake the pizza can have a significant impact too, but for starters I'm guessing that you might be opening the dough skins too thin as this will result in a tough and chewy crust almost every time. Make another dough and when opening the dough into a skin experiment with different

(thicker) skins. Thin cracker doughs are made much like a pie dough and as such I really wouldn't call the dough "soft" by any stretch of the imagination, this is why it's important to know your dough formulation as well as procedures used in making and baking it.

[Re: My tough Dough](#)**2714**

Place the basil leaves on IMMEDIATELY after removing the pizza from the oven, the heat will wilt the basil and release the flavor with no chance of charring it.

[Re: Slightly under-proofed?](#)**2715**

1) Was there any sugar, eggs, milk, etc. in the dough formula?

2) Were you baking just undressed dough skins into par-baked crusts?

Typically what happens is that the thicker stone holds more latent heat thus not giving up as much of its heat to the pizza during baking so the bottom temperature remains more constant during baking thus providing a stronger bottom bake and the real test is when you place a second pizza on the same spot right after baking the first pizza.

If those were just crusts as they appear to be you most likely were not pulling much heat out of the stone so thickness wasn't as critical.

[Re: Different thickness stones get the same result?](#)**2716**

Both PJ's and Domino's use air impingement ovens to bake their pizzas. The disks will NOT bake the same, or anything close, in any type of a deck oven as they do in an air impingement oven. I'm in agreement that your best bet might be to begin the baking process on a silicone baking sheet and then remove it after a couple minutes to finish baking right on the steel deck.

[Re: Pizza baking sheet on top of steel](#)**2717**

SG;

Temperatures in the 90's as well as high humidity won't hurt the dough at all as it is essentially a no-time/short time dough process. I would recommend using cold water (50F) to make the dough as this will prevent getting a finished dough temperature above 90F which should be avoided if at all possible.

Once mixed allow the dough to ferment for a minimum of 2.5-hours (can easily go as long as 6-hours at room temperature under your conditions) before opening the dough balls into skins.

[Re: Same Day Dough](#)**2718**

Due to the fact that you are using a sourdough starter at a high level, that's about par for the course.

[Re: Flat squares instead of round balls](#)**2719**

Actually, 0.1-ounce = roughly 2.84-grams, not good for small dough sizes but OK for larger doughs, however in reading through some of the questions/answers I see a comment that it won't respond to less than 4-grams on the pan. I don't know if that means you need at least 4-grams on the pan to get it to respond or not. If so the tare of a container should take care of that. Would sure like to see a report back on this scale if anyone has one yet.

[Re: good deal on food scale](#)**2720**

That would be correct, just so long as it's food grade.

[Re: Salt crumbs in the dough](#)**2721**

I'm not overly fond of the vertical viewing of the display screen but for the price I'd be willing to overlook that one objection. Look mom! No more excuses for not weighing the ingredients! :)

[Re: good deal on food scale2722](#)

That sounds more like rock salt. Why not just use a finer grade of sea salt?

[Re: Salt crumbs in the dough2723](#)

I also like to tear it apart (I liken it to peeling an orange) as this gives me the necessary thin pieces.

[Re: Beginner mozzarella cheese question2724](#)

Just remember that CY has a limited shelf life (about 3-weeks) for home use and 2-weeks for pizzeria use, after that time it will begin to deteriorate showing progressively poorer fermentation properties and depending upon storage conditions, softer, weaker, more extensible doughs. CY must be held under constant refrigeration especially in warm climates (remove from fridge, weigh amount needed and immediately place back into the fridge). Keep in mind that depending upon your source/supplier, the CY may be anything from a few days old to well over a week old already so if you see deterioration in the yeast or in your doughs you will need to adjust the shelf life (time you can store the CY) accordingly.

[Re: Activation of the CY and temperature targeting2725](#)

Here's the easy way to work with VWG;

1) Determine how much you want to increase the protein content of your existing flour.

2) Divide that number by 0.6 and that is the percent VWG you will need to add to whatever amount of flour you are using to bring the protein content up to whatever percent you wanted.

Example:

Your existing flour has 11% protein content and you want to increase it to 12.5% protein content. $12.5 - 11 = 1.5\%$ protein increase is desired. 1.5 divided by 0.6 = 2.5% VWG will need to be added to your flour to bring it up to the targeted 12.5% protein content.

NOTE: For each 1% VWG added to the dough you will also need to increase the dough absorption by 1.75%.

To add the VWG be sure to dry blend it into the flour using a whisk, just a few stirs with the whisk will be sufficient to disperse the VWG into the flour.

One other cautionary note:

There are different types of gluten, there is vital wheat gluten (VWG) and devitalized wheat gluten (DVWG), THEY ARE NOT THE SAME AND PERFORM VERY DIFFERENTLY.

There is also corn gluten which is NOT the same as VWG, in this case the word "gluten" is synonymous with protein so corn gluten is nothing more than corn protein and since there is NO glutenin or gliadin in corn protein it will not perform as VWG.

[Re: High Gluten Flour 2726](#)

With regard to rate of fermentation it doesn't make any difference if the salt goes into the dough early or late in the mixing stage, all it's affecting at the mixer is the

speed at which the gluten develops but since in pizza dough production we are not trying to achieve much gluten development it's a moot issue.

[Re: Salt crumbs in the dough](#)2727

Why are you trying to activate yeast that is already activated? If you are machine mixing just crumble it into the flour and begin mixing, if you are hand mixing just place it into the dough water, regardless of temperature (within reason of course) and whisk it to achieve a yeast suspension, just takes a few seconds, then pour the yeast suspension into the mixing bowl and you're good to go.

[Re: Activation of the CY and temperature targeting](#)2728

The salt will most likely dissolve in the water that it will pull from the dough and subsequent handling of the dough will take care of the dispersion of the salt. The worst thing that might happen is that you could get pronounced salty flavors if the dispersion is poor. When we use the delayed salt addition mixing method the salt is added right at the beginning of the last four minutes of the mixing cycle BUT the salt used in this application is a very fine salt (small particle size) which aids in both distribution and dissolving of the salt in the dough.

[Re: Salt crumbs in the dough](#)2729

The answer is "osmotic pressure".

Yeast feeds through osmosis and when you have much more than about 2% sugar in the dough it upsets the osmotic pressure around each yeast cell thus hindering the cells ability to draw nutrient through the cell wall membrane. If you were to place CY and sugar together (in direct contact with each other) the osmotic pressure exerted by the sugar (or salt) would be so great as to plasmalize the yeast by pulling the plasma (glutathione) out of the cells and giving you a brown sticky syrup. This is why we increase the yeast level in sweet doughs containing high levels of sugar (18 to 25%), if we didn't it would take forever to ferment and proof the dough.

[Re: A question about sugar saturation](#)2730

Oh my, sooo many things to consider;

Can you ferment the dough longer?

Can you use a lower protein content flour? Remember, N.Y. pizzas are made using All Trumps flour (14+% protein content) to achieve that chewy mastication property).

Make the dough skin a little thicker (use more dough to make the same size pizza). Consider using oil in the dough.

Reduce or eliminate sugar fro the dough formula.

Bake longer at a lower temperature.

Use less sauce (try using thin slices of fresh, ripe tomato instead of your regular sauce as a test but be sure to VERY LIGHTLY brush the skin with oil before application of the tomato slices).

Dough absorption should be maximized for the flour being used (softer dough = crispier crust).

Depending upon oven spring characteristics of your dough, a SLIGHT increase in yeast level might provide more oven spring resulting in a better overall bake = reduced toughness and crispier crust characteristics.

If hand opening make sure not to get thin spots in the dough skin.

This is a good starting point for things to consider. All of them probably won't apply to your dough so you might be able to eliminate some right from the start, any not eliminated will need to be explored through testing. I see more pizza parties in

your future :chef:

[Re: Chewy dough](#)2731

A cold dough going into the fridge will experience significantly less fermentation before it drops to 40 to 45F where yeast is relatively dormant than a warmer dough. There seems to be a point which appears to be at around 70F where, with a correctly functioning cooler, the dough will exhibit little gain in volume over the CF period. A dough of this type, unless exposed to CF for over 3-days or given a lot of post refrigeration proofing prior to opening, would be tougher than a "normally" fermented dough. Temperature is the number one driver of fermentation.

[Re: tough dough question](#)2732

Just be sure to use metal utensils, not wood or plastic.

[Re: Avoiding cross contamination between starters](#)2733

The process you have outlined is very similar to what I've seen done commercially. The par-baked crusts can be stored for a full day or more without any issues, just store at room temperature, not under refrigeration. Once you have an inventory built up you will be working from that inventory and making more par-baked crusts during the day. My advice is to work against a fixed daily inventory.

[Re: Help with forming pan pizzas with high hydration dough](#)2734

So, let me see, you're proposing to add the garlic after baking? Why not just add it to the pizza, on top of the dough just prior to application of the sauce or as an ingredient when dressing the pizza?

[Re: Don't know what i'm doing wrong at the moment](#)2735

Commercial pizzerias accomplish it through the application of a special starch wash to the crust prior to baking. This starch is available from National Starch Company (Decatur, Illinois?). You can get another form of this but to a MUCH lesser magnitude and without the color from a cold dough, this is why we see it on crusts made from frozen dough.

[Re: What causes dough to do this, and how to replicate](#)2736

#4 is only performed after the dough has been fermented for a period of time and it works much better on a large dough than a small one such as is typically made by home pizza makers. The purpose of punching the dough is as follows:

- 1) To keep the dough in the container.
- 2) To help equilibrate the dough temperature.
- 3) To provide additional nutrient to the yeast.

[Re: The importance of mixing](#)2737

Here is a little tip;

When buying a dial/stem bi-metal type thermometer look for one with a hex nut located on the underside of the dial. This is the calibration adjustment. If it doesn't have one, save your money to buy one that has it. To calibrate use an oral thermometer (calibrated for 98.6F) then place into a bowl of water and adjust the temperature until you get a reading close to 98.6F, compare this temperature against your shop thermometer and adjust as necessary. This method is much better than using ice water since the calibration temperature will be closer to the actual working temperature of the thermometer making for more accurate readings.

[Re: A man with 1 thermometer knows what temperature it is....](#)2738

I always put just a very thin coating of oil in the container and the dough ball just plops right out. When you "flour" the dough ball and place it into a container the flour just hydrates and becomes one with the dough, serving no useful purpose unless you have a very low absorption dough. As for the "window pane" test for gluten development, pizzas doughs are not mixed to full gluten development, they are mixed JUST to a point where the dough takes on a smooth appearance....no need to mix any more, so the gluten test is best left for the bread bakers who need to develop their bread dough to a much greater level of gluten development.

[Re: Oiling/flowering dough balls surface & gluten test?2739](#)

QJ:

Now you know why I always say to "record" the finished dough temperature for each and every dough :).

Don't worry, that's how we learn our most important lessons.

[Re: tough dough question2740](#)

Yes.

[Re: Why is my dough doing this?2741](#)

Remember that the garlic powder is also weakening the dough in addition to the fermentation so unless the fermentation chart is designed around YOUR specific dough formula and YOUR specific flour you should only use it as a guide, nothing more. Different flours exhibit a different tolerance to fermentation (a characteristic of the variety of wheats (grist) the flour is milled from). This is where YOUR fun begins!

Experiment with different dough temperatures (colder doughs ferment slower than warmer doughs) as well as different yeast levels (less effects of fermentation on the dough with lower yeast levels), and don't forget about the dough absorption too, while you might get an initially firmer dough with lower absorption it will exhibit greater strength characteristics and be easier to handle after the fermentation period. :chef:

[Re: Don't know what i'm doing wrong at the moment2742](#)

Remember how GOOD McDonalds French fries USED to taste? That's because they WERE fried in beef tallow, but now since tallow is not consumer friendly they are frying their French fries in a different fat (I believe it used to be a blend containing a good portion of palm but I don't know what they use today).

I find it amusing how good people find the food to taste when they make it like it used to be made back in the good old days when food was good...yes, it has changed.

[Re: Beef Fallow2743](#)

First of all, oil does not make the dough more "elastic" (create more "snap-back") but to an extent it does contribute to the extensibility of the dough. This is due to the oil's ability to lubricate the gluten allowing for easier stretching of the gluten/dough especially during the critical phase of oven spring. As for elasticity and extensibility, you are correct in that they cannot be used as synonyms as you have correctly stated:

Elastic/elasticity: The ability of the dough to pull back (snap-back) to regain its original shape after being pulled or deflected in shape.

Extensible/extensibility: The ability of the dough to retain its new shape after being pulled or deflected into a new/different shape.

The under fermented dough exhibited a very elastic characteristic while the over fermented dough was too extensible to handle easily.

[Re: Why does oil make dough elastic?2744](#)

Place your hand into the flour with your fingers spread apart and rake your hand through the flour, after capturing and clumps in your hand bounce your hand up and down, if the clumps break apart and just filter out between your fingers, all is good, if they appear to bridge the gap between your fingers and the flour appears to be stringy you have an infestation problem with Indian meal moths. If any question send us some pics.

Additionally, if you sift the flour and it all goes through the screen you're good but if it builds up on the screen the flour is infested as the flour particles are adhering to the moths web.

[Re: GM Gold Neapolitan Flour 2745](#)

I'm not sure I understand your question but if it is in regard to needing to use a short fermentation time to achieve an open, porous crumb structure, just the opposite is true. To achieve a very open crumb structure a long fermentation time is used. Compared to bread doughs, typical pizza doughs receive considerably more fermentation.

[Re: Additions to Your Dough2746](#)

OK, now that the "whole" story has come out, the Thai dragon peppers/Thai chili flakes will probably be your best bet as it will provide the type of flavor your customers will be able to relate to.

[Re: How would you go about making a very spicy sauce?2747](#)

In reading the attached link one of the problems that I see is that they are continually vacillating back and forth between bread dough and pizza dough. The technology employed in making bread dough is significantly different from that used to make pizza doughs. I had to chuckle when I read the amount of ascorbic acid recommended.....it's measured in parts per million (ppm). A typical dose of A.A. is in the 30-ppm to 90-ppm range with maximum doses running at or close to 200-ppm. Granted, there is no Federal maximum use level for the baker to add (there is a limit to how much a flour miller can add) but there is a point of diminishing returns which comes in at around 200-ppm.

Lecithin, whether it comes from soy or eggs (yolk) is not a recommended ingredient in pizza dough as it is an emulsifier (binds water and fat together) so when lecithin is used in the dough the water is more difficult to bake out but more importantly the fat in the dough now binds the water rather than repulsing it which can be a major contributor to the development of "the dreaded gum line".

[Re: Additions to Your Dough2748](#)

Red chili pepper flakes and if you want more try using jalapeno, serano, anaheim, Thai dragon peppers are also good (Thai chili flakes), and there's always habaneros.

Put whatever chilis you opt to use into a bowl, add a little oil and nuke to heat the oil thus extracting the good stuff from the seeds, then blend into your sauce.

[Re: How would you go about making a very spicy sauce?2749](#)

I try to slice mine between 1/16 and 1/8-inch thick. Being precise at cheese slicing

is not my forte.

[Re: Cheese for Deep Dish](#)**2750**

If the dough formula came from a local retail baker it was more likely than not something pretty close to that of a French bread dough formula (100% flour; 2% salt; 55% water; 1% compressed yeast; and maybe 1 or 2% oil). Nothing special as you can see, but if this all took place many years ago (30 or 40) there is a good possibility that he was using a direct dough process where he would mix the dough in the morning, allow it to ferment at room temperature all day, knocking it down if necessary, and then around 7:00 p.m. grab a hand full of dough, cut it free using a knife, flour the dough piece (DO NOT BALL), pass it through a dough sheeter two or three times, trim it to desired diameter, dress and bake. The trim scrap was saver for use later in the day/evening if necessary, if it wasn't needed it was added to the next new dough as scrap and the process repeated.

Can you provide a time frame as to when they opened?

[Re: Pizza Dough](#)**2751**

This is essentially the same procedure that we taught all of our seminar students to use. It is, by far, the best procedure to use when dividing a large dough (think pizzeria). What you do is cut the first piece and weigh it, then based on the actual weight cut the next piece longer or shorter and weigh again, when you have the correct length to give you the desired weight "fire for effect" meaning that you can cut a number of pieces and have them at or very close to the target weight. We used to make a contest out of it to see how many pieces each of us could cut that were "spot-on" weight wise. My personal best was eight (8) pieces. By using this method one person can divide 80+ pounds of dough into individual pieces weighing 9 to 12-ounces each, in 20-minutes or less. No other hand cutting method will allow for this speed.

By the way, remember those delicious bagels you used to buy? All of the bagel formers are fed dough which is mechanically divided by the exact same procedure, an operator cuts the dough into "ropes" of about 3-feet in length and places it onto a narrow conveyor, then a cutter automatically cuts the dough to a length which provides the correct dough weight for the type of bagel being made. The dough pieces in this case are referred to as "plugs". Something to watch for the next time you're in a bagel shop. :)

[Re: Dividing Dough - New method \(for me\)](#)**2752**

I totally agree with Steve's approach. A few things to keep in mind; With an ash content of 0.78% (not 78%) the amount of whole grain is quite high. The bran content of the whole-wheat portion exerts a cutting effect upon the gluten as it is forming which weakens it significantly, this is why vital wheat gluten is commonly added to doughs of this type as it provides the needed strength to be able to handle the dough after fermentation. Under the best of conditions I seriously doubt that you will be able to get more than 48-hours usable life from a dough made entirely with this flour. Due to the acidity of a sourdough there is additional weakening of the gluten so the dough strength is again being compromised.

Steve's suggestion is a good one, first learn to make decent dough using that flour without the addition of any sourdough starter, then after you have accomplished that, begin introducing increasing levels of sourdough starter (5% increments?) to see if the dough retains its integrity with your improved dough handling experience.

Also remember that dough made from a flour of this type will typically require a higher absorption than a dough made using white flour. This is due to the hydration

properties of the bran which is present in greater quantity in your specific flour. Remember too that bran hydrates much more S L O W L Y than the protein and damaged starch in the flour so it is not uncommon to see a dough which feels great when mixed become hard or firm and difficult to handle after 30 to 60-minutes. If you go back through the archives here you will find discussion in which I outlined the procedure for finding the correct dough absorption to use with flours of the type which you are using.

[Re: Sourdough dough too friable2753](#)

QJ:

If you want to make a dedicated 3 to 4-day dough try this:

Reduce the finished dough temperature to between 65 and 70F.

Use normal yeast level (I use 0.375% IDY)

Manage the dough as per my printed procedure.

The dough will NOT be ready to use before 48-hours but it will be good at 72 and 96-hours.

[Re: tough dough question2754](#)

I'm guessing that your IDY level was too low as 0.58-ounce per 50# of flour weight calculates out at only 0.0725% while a typical IDY level would be between 0.25 and 0.4% (2 to 3.2-ounces).

[Re: Instant yeast vs. Compressed yeast2755](#)

My oldest son is half owner of a large landscaping company in Olathe, KS and he owns a farm where they work out of, because of all the nursery stock he has an interest in keeping the insect population in check and to do that he encourages birds and bats to take up residence on the property. My part of this scheme is to keep him supplied in bird houses, bat houses, and bird feeders. One of his contractors installs a lot of privacy fencing and he saves his cut-off scraps for me to use in building the houses and feeders. With all of his vehicles he has a regular supply of license plates for me to use for roofing materials on many of the houses. A quick trip over to the local resale store always provides materials to use from chain to wire, to drawer pulls for perches, to small hardware such as hooks and eye bolts for next to nothing, then when I'm not building them I'm repairing them. If anyone wants to see pictures of these just P.M. me with your e-mail and I'll be glad to forward them to you from my phone.

[Re: Clear birdfeeder for window2756](#)

How much of what kind of yeast were you using?

[Re: Instant yeast vs. Compressed yeast2757](#)

My experience is that a well managed CF dough will have a maximum use life of 3-days with 4-days on the outside. The yeast seems to deplete its nutrient between the 3rd and 4th day. This results in the yeast beginning to cannibalize itself thus releasing glutathione into the dough which weakens the dough as well as making it feel tacky and lack the desired amount of oven spring. With an added 2% sugar to the dough formula it's possible to stretch this out to a maximum of seven days.

Whey can be included in a dough formulation for the purpose of providing crust browning even with long fermentation times (whey is 70% lactose sugar which is not fermentable by bakers yeast).

[Re: tough dough question2758](#)

There was once a place actually called "Cold Pizza". Just ask any college student

what the "other" name for cold pizza is....BREAKFAST.

Sure cold pizza is different from fresh pizza but never enough to cause me to turn my nose up at it...it's still good! If I'm going to reheat my pizza I've found that just "nuking" it for 30-seconds and then placing it in a hot frying pan to reheat and crisp up the bottom works well for me, sometimes I just nuke it for 45-seconds and eat it like it is, yes, the crust will be soft, but the whole thing will be acceptably warm and still "not bad".

I guess I'm just not a Pizza Snob"....I like it all, granted some more than others.

Like I always say"I've never had a pizza that I couldn't learn to like". ;D

[Re: A question about reheated pizza.](#)**2759**

The only difference between Crisco, lard and beef tallow is the flavor imparted by each. NOTE: Essentially all lard sold outside of a specialty food shop will be deodorized lard, this means all of the flavors associated with lard have been removed by a distillation process which renders the lard essentially flavorless as compared to that which you get in Mexico or a specialty food shop selling non-steam distilled lard. Beef tallow imparts its own unique flavor as long as it hasn't been steam distilled. Crisco, made from vegetable oils is designed to have a neutral flavor (that's another way of saying it's flavorless). By the way, tallow, because of its high melting point (about 135F) needs to be melted and slowly added or it will crystallize as it contacts the cooler dough/ingredients thus forming lumps of hard tallow that cannot be mixed out of the dough.

[Re: Beef Fallow](#)**2760**

You might want to run your question across George Mills over at the PMQ Think Tank <www.pmq.com>. George is the resident expert on ovens over there.

[Re: Blodgett 1000 Aftermarket parts/mods?](#)**2761**

The seller of your pan gave you excellent advice to "season" your pan prior to use. Remember, DO NOT wash a seasoned pan, and NEVER allow it to soak in soapy water, NEVER, NEVER. If you do the seasoning will begin to peel off like a bad sunburn and you will need to strip all of the remaining seasoning off of the pan and start all over again :(. Don't worry about the dough "smelling bad" that's probably just the aroma of fermentation (a good thing). If your dough is fermenting too fast you will need to reduce the amount of yeast used in your dough formulation.

[Re: Don't know what i'm doing wrong at the moment](#)**2762**

Wood prep peels are much better than most metal peels. Metal peels should always be used to remove the pizzas from the oven.

[Re: Anyone use parchment paper like this?](#)**2763**

A couple of questions come to mind;

- 1) What type of surface are you baking your pizza on?
- 2) What color is your aluminum pan? Bright, dark anodized, or dark seasoned?
- 3) Why not allow the dough to warm to at least 50F/10C prior to opening?

[Re: Don't know what i'm doing wrong at the moment](#)**2764**

Now that looks good enough to eat! :)

[Re: Swimming upstream with NP hybrid dough?](#)**2765**

Your common tap water, just so long as it doesn't smell like sulfur, should be just fine. Those minerals are good for the dough just as they're good for us. The most important aspect of the water you use is the temperature of the water, that's how

the finished (mixed) dough temperature is regulated. For the most part, CF doughs will require a finished dough temperature in the 70 to 75F/21.1 to 23.8C range while RT doughs may perform best with a finished dough temperature in the 80 to 85F/26.6 to 29.4C range. As you will soon find out as you begin experimenting just about everything is variable to a degree when making pizzas, this is why we call them "rules" of formula balance not "laws" of formula balance. When it comes to dough management there are also great differences in how the dough is managed, some with good results, some with not so good results, this is something that you will need to work out for your SPECIFIC dough formulation and desired end results (that's the fun part) :chef:

By the way, I believe Peter has the function of ingredients cataloged, he should be able to direct you to them with his magic wand, he's the best of the best when it comes to searching for something here.

[Re: Don't know what i'm doing wrong at the moment](#)2766

Is it possible that your oven, as you said is so well insulated that it reached set temperature where the thermostat probe is located but the stone had still not fully come to temperature, the burner would then shut off but the stone would continue sinking heat from the oven chamber thus dropping its temperature?

Just a "SWAG".

[Re: Home oven. Stone dropped in temp after setpoint was reached](#)2767

QJ;

Keep us posted.

[Re: tough dough question](#)2768

Good point! A long mixing time can result in a tougher than normal eating characteristic. It's not a big deal where the salt is added when making pizza dough as the salt delays the gluten development, this is why large commercial bakeries almost universally use the delayed salt mixing method (the idea being to reduce total dough mixing time as much as possible). By this method the dough is mixed normally and at a point approximately 4-minutes before the dough is completely mixed, the salt is added and incorporated during the final four minutes of mixing.

[Re: tough dough question](#)2769

They didn't provide a dough formula for you to work with?

Here is one to get you started:

Flour: Bread flour (11% protein content) 100%

Salt: 2%

sugar: 3%

IDY: 1%

Water: 58% (variable)

Hard fat flakes: 10% If you cannot source hard fat flakes use butter, margarine or shortening, place it into the freezer until THOROUGHLY frozen, then shave it and place the shaved pieces back into the freezer for about 30-minutes, then chop the shaved pieces into flakes with the largest being about 8-mm in width. Place the shortening back into the freezer until you're ready to use it for making the dough. The shortening can be prepared well in advance and stored in the freezer. The reason for doing this is to achieve a desirable open, course (porous) crumb structure.

Procedure:

Place water in mixing bowl (70F/21.1C) followed by salt and sugar then the flour

and the IDY. Mix the dough at low speed for 2-minutes then at medium speed just until the dough begins to look smooth, change back to mixing at low speed and add the frozen fat flakes and continue mixing JUST until they are thoroughly incorporated, take the dough to the bench for scaling and balling. place the dough balls on lightly oiled sheet pans and cover with a sheet of plastic, allow to proof at room temperature until the dough forms smoothly without tearing or fracturing. If the dough needs to be softer/firmer adjust this by adding more or less water. Normal fermentation time for the dough balls is about an hour.

NOTE:

If you do not want to have the more open, porous crumb structure you can use and high quality shortening, butter or margarine to replace the fat flakes.

When building the cone put a small amount of sauce in first, then the meat and/or vegetable toppings with the cheese on top. DO NOT OVER FILL. You will also need to have a form for holding the cones upright for baking.

[Re: pizza dough recipe for cone pizza machine](#)2770

If they are making an emergency dough as you've described the garlic powder would make perfect sense as it would provide the necessary extensibility normally provided by fermentation for opening the dough into skins. As for the yeast level, 12.5-grams per kilo of flour would be a good starting point for such a dough. Mix the dough to a smooth consistency/appearance plus 3 additional minutes at medium speed or 5 minutes at low speed. The idea here is to achieve more gluten development through mechanical mixing as it will not be achieved through biochemical gluten development as there will be no fermentation period.

Immediately after mixing scale, ball, and lightly oil the dough balls, set aside and cover with a sheet of plastic and allow the dough to rest at room temperature until ready for use (60 to 90-minutes). One other thing, be sure to adjust the dough water temperature so as to achieve a finished dough temperature in the 90 to 95F range. Remember, this dough is going to be moving FAST, when it's ready for opening it's time to get busy...it will NOT wait for you.

[Re: Don't know what i'm doing wrong at the moment](#)2771

QJ;

Assuming the oven is properly set-up for the gas that you are using, the Marsal ovens just don't have a recovery issue (huge burner capacity and thick decking). But if the dough is being over fermented resulting in collapse of the center section of the pizza due to the weight of the toppings the pizza WILL NOT bake properly resulting in a guaranteed tough, chewy finished crust with about as much crisp as a wet noodle. 550F is a good baking temperature for what you are trying to achieve. The oven will take about 2-hours to come up to full baking temperature from cold (that thicker deck takes some time to completely heat up).

[Re: tough dough question](#)2772

If you are using 2-ounces of CY (compressed yeast) you would replace it with 16.47-grams of IDY (instant dry yeast) or 1-ounce (28.4-grams of ADY (active dry yeast). Your math is correct :).

Regardless of the type of yeast being used, the dough should be scaled, balled and into the fridge within 20-minutes of completion of dough mixing. Remember to adjust the water temperature to give you a finished (mixed) dough temperature in the 75 to 80F range. Most of the time this will require water at 65 to 70F. Don't forget to cross-stack for at least 2.5-hours, then down-stack for the remainder of the cold fermentation time.

This will give you the most consistent dough possible for use in a pizzeria over a

three day period.

[Re: Instant yeast vs. Compressed yeast](#)2773

QJ;

By chance, do you have an external gas pressure regulator installed in the gas line just prior to the oven?

[Re: tough dough question](#)2774

Yeast that is actively feeding (fermenting) does not tolerate freezing as well as yeast that has either not yet begun to ferment or has been fermenting for a shorter time. In essence, the sooner you can freeze the dough after mixing the better it will be. Studies have shown if you can freeze the dough before it has received 4-hours of fermentation you can expect to get up to 10 to 14-days of frozen shelf life, if you are only wanting to freeze the dough for a few days to a week on the outside you can freeze it at any point while the dough is still in good condition and the yeast is still actively fermenting. The best way to freeze the dough is to make flattened out dough balls (pucks), lightly oil the dough, wrap only once in stretch wrap and place into the freezer until solidly frozen (this will take 4 to 6-hours depending upon dough temperature and size) once thoroughly frozen the dough puck can be wrapped more securely with stretch wrap. To use your frozen dough, remove from the wrapping while still frozen, place into a suitable container and put into the fridge for at least 16-hours to slack-out (thaw), then bring out of the fridge and allow to warm for use or if you wish you can allow the dough to warm to 50F and then place it back into the fridge to cold ferment for whatever time you wish, just be sure to remove the dough from the fridge and allow it to warm to 55 to 60F before opening it into a skin.

[Re: When to freeze?](#) 2775

That's quite some dough formulation.

I would suggest reducing the IDY by 50% (use only half of what you're presently using. Then I would highly recommend eliminating the garlic powder since it is a reducing agent, meaning that it causes the dough to become soft, weaker and more extensible.

Start with those two changes and let us know how it works for you.

[Re: Don't know what i'm doing wrong at the moment](#)2776

A uniform golden hue on the crust is usually due to brushing the skin with olive oil immediately prior to baking...sorta like using an egg wash on a pastry dough to achieve the same effect on crust color. If semolina flour was used the crumb will also have somewhat of a yellowish tint to it.

[Re: High gluten flours to try for NYC style pizza?](#)2777

I don't like using oil to get the sesame seeds to adhere as they do not adhere well using the oil and just end up falling off unless handled very carefully. For home use it's probably OK but in a pizzeria application the water works better.

[Re: Sesame seeds](#)2778

I love to use sesame seeds on the bottom pf the pan when making any pan style pizza for the toasted sesame flavor they provide. If you lightly brush the edge of the crust with water immediately before baking you can sprinkle sesame seeds onto the edge crust where they will be toasted lending the same effect to any pizza. We have also carefully ground toasted sesame seeds using a food processor and blended the meal into the flour for a unique flavor in the finished crust (Note: when

used in this manner the seeds must be toasted or a bitter flavor will be your only reward).

[Re: Sesame seeds](#)**2779**

Do you have the Konos machine?

[Re: pizza dough recipe for cone pizza machine](#)**2780**

Black pudding and eggs! My favorite!! :)

[Re: This evenings attempts](#)**2781**

Assuming equal times the dough with room temperature fermentation will receive significantly more fermentation than the same dough cold fermented for the same period of time. With the greater amount of fermentation it would make sense that the room temperature fermented dough might have more of the aromatic compounds formed during fermentation, hence your observation of a different aroma. Taste on the other hand, is a result of acids formed during the fermentation process as well as sensitivity to specific tastes (we all taste things differently). This is why we talk about "flavor" a combination of taste and aroma, as opposed to just taste.

As for the difference in crispiness, it is well recognized that there is a link between increased crispiness and fermentation, but like everything else, it has its limitations, just like there is a link between increased dough absorption and increased crispiness.

As for a dough subjected to a 48 to 72-hour CF it has been my observation that our doughs (remember all doughs are different) are at their prime for producing great finished crusts at 48-hours and are still quite good but are beginning to exhibit some handling issues after 72-hours CF, mind you, this is based on a pizzeria environment, using my dough management procedure, bough boxes, a walk-in cooler and opening the dough balls into skins by hand.

[Re: RT ferment Question](#)**2782**

Why salad oil instead of "20Xvirgin" olive oil? You can use olive oil if you wish, I just like to save my good olive oil for use on the pizza immediately after baking where you will get a significant flavor contribution so I use the cheapest stuff I have on hand to oil the dough balls and/or the dough container, call me cheap, call me practical, just DON'T call me late for pizza! ;D

[Re: Tough Dough](#)**2783**

When it comes to sourdough starters it's all about trial and error. All sourdough starters, unless inoculated with a known starter, and meticulously maintained, will vary in strength and composition. Once you have your sourdough made and you're successfully maintaining it you will need to experiment with the amount to use to make the pizza you are trying to achieve using YOUR specific dough management procedure. There are MANY posts here from individuals who have mastered the cultivation of a sourdough starter but have found like other things in life, it seems to have a mind of its own when it comes to amount to use. While one source might say to use 5% with your starter you need to use 20%, that's just the way it is. Then too we hear about someone who has had their starter going for some time and now it seems different, like I said...mind of its own. In some cases the microflora of the starter can change resulting in a totally different, and unexpected outcome. In cases like this sometimes it can be recovered or you may just need to start all over again and because it is the luck of the draw as to what the microflora will consist of

the flavor may not be exactly the same, ditto for the use level.

[Re: Poolish vs. Biga vs. Criscito](#)**2784**

The correct direct substitution of IDY for CY is 29%. This means that the amount of IDY needed to replace any specific amount of CY will be 29% of the weight of the CY.

As you are asking about a dough based on 50# of flour weight I'm assuming you're asking in reference to use in a commercial/pizzeria application. In this type of application allowing the dough balls to proof at room temperature prior to placing them in the cooler is not a preferred method as it can significantly contribute to inconsistencies in the dough which can result in dough failure (failure is not an option in a pizzeria) or variation in the finished pizzas (good or bad) which will be recognized by your customers with less than desirable results.

If you have specific questions or if you can provide more details I'm sure we can help you.

[Re: Instant yeast vs. Compressed yeast](#)**2785**

Jon;

What can you tell us about your dough formula, how you're mixing it (sounds like your hand mixing but we need the details) and how you're managing the dough. Caputo "00" flours are significantly lower in protein content and are not as strong, gluten wise, as All Trumps flour which has a typical protein content of just over 14%. More than likely dough absorption will need to be increased, mixing changed as well as some changes possibly in dough management to get more fermentation on the dough to address the stronger gluten characteristics of the A.T. flour.

[Re: Tough Dough](#)**2786**

Good grief! We have discussed this topic at great length, all one needs to do is to spend a little time looking through some of the recent posts. By the way, those discussions were excellent and should help anyone not familiar with all of the different types of "pre-ferments" and how they impact dough rheology and finished product characteristics including flavor and aroma become better versed on aspects of making them, using them and how they will impact the finished crusts.

[Re: Poolish vs. Biga vs. Criscito](#)**2787**

Yeast is not typically used in the autolyse but it is used in the poolish and biga. The poolish is used to great extent in the commercial baking industry where it is known by a different name "brew" or "liquid ferment" or "liquid sponge". Brew is the most common term for it. In this application the brew is fermented for 2 to 6-hours under highly controlled conditions, it is then passed through a heat exchanger and brought down to 40F or a little less and maintained under these conditions with sweep agitation (1 r.p.m.) to prevent settling and used over the course of several hours of production with a specific amount metered into each dough at the time it's mixed.

[Re: Autolysis](#)**2788**

RPF;

The typical use level for a "typical" dough formula is 1% compressed yeast. This works well when using up to 3-days CF (dough actually is in its prime at 2-days/48-hours). While some may argue that there is a difference in finished product flavor resulting from the type of yeast used our research has shown that there is no difference in flavor PROVIDING the dry forms of yeast are used correctly AND it is used at the CORRECT substitution level. I think this is why some people think there

is a difference in flavor.....it is used at the wrong substitution level which results in a different fermentation rate resulting in a different flavor profile in the baked product.

[Re: Fresh yeast?2789](#)

Hey man! My brains get scrambled better than my breakfast eggs after a long day in the saddle too :-D.

Tim won't be doing anymore videos as he has retired from General Mills but Bill Weekly will be carrying the torch for him.

[Re: Baker percentages2790](#)

Actually, it has little to nothing to do with the gluten, it's all about getting the flour hydrated. If the flour is hydrated during the mixing process it adds about an additional 2-minutes to the mixing time (important in a commercial bakery). Gluten is formed when the flour proteins (flour) are agitated in the presence of water, in order for the gluten to be formed those proteins (glutenin and gliadin) have to be hydrated. This is where the autolyse is incorrectly said to develop gluten, it aids rapid gluten development but it does not specifically develop gluten. Salt and sugar will compete for the water and exhibit more osmotic pressure than the wheat proteins so either of these ingredients will slow the migration of water into the wheat proteins. This is the very same reason why in a commercial baking application a mixing procedure called the delayed salt mixing procedure is almost universally used today, it is also why when making pastry doughs such as sweet dough and Danish dough the sugar and salt are never added right up front, they are held back until the gluten has reached the desired stage of development. An autolyse will also improve the dough handling properties of a high absorption dough as it allows the use of a higher dough absorption than what could be used if just adding all of the water at the time of mixing.

[Re: Autolysis2791](#)

In referencing "reduce the dough absorption" means to reduce the amount of water added to the dough/use less water when making the dough. Try LIGHTLY oiling the bowl and I think you will find that the dough comes out a lot easier.

[Re: Help with Ankarsrum kneading, please! My Neapolitan dough won't relax.2792](#)

Saturation? I think he may had said "absorption" which is a common term for the amount of water added to a dough. The amount of dough absorption used will vary with the type of pizza/dough you're making, for example, it can be as low as 35 to 45% for some cracker type crust doughs and in the high 60's to low 70's for Neapolitan pizza doughs to be baked in a very hot oven. On average, most pizza doughs will come in at about 62% dough absorption. The amount of yeast given is in line with compressed yeast (CY) for an average pizza dough. This is why it is important to ALWAYS know what type of yeast is being used or recommended. While many pizza dough formulations don't contain any oil or not much more than 1%, 2 to 3% oil is not out of line with what many like to refer to an an American style pizza. Again, when discussing dough formulations one has to know what type of dough/pizza is being discussed.

[Re: Baker percentages2793](#)

Well, let's go with the 4-hour food safety rule. Following this you can bake your pizzas and hold them for up to a total of 4-hours at a temperature under 140F and above 40F. So you can bake the pizzas and store in an insulated cabinet then transfer to the temperature/humidity controlled cabinet for display and warming as

needed.

[Re: Reheating slices in a food truck?2794](#)

Agreed, just plug in the unbromated flour and go on with life. No need to mix any differently, absorption stays the same (assuming the same flour just unbromated). The only place where you "might" see a slight difference is our at five days or so, but I don't think there are many pizzerias holding their dough that long (yes, the big box chains do but they manage their dough using excellent temperature control as well as a very effective dough management procedure that is built around the use of unbromated flour). For a typical pizzeria using a bromated flour and managing the dough out to 3, 4-days max, and changing over to an unbromated flour it is basically a "plug and play" proposition.

[Re: Unbromated flour?2795](#)

Reduce the dough absorption to control dough flow during the fermentation process. Flouring the bowls will not work as the flour will just pull moisture from the dough turning it into "school paste"....not exactly a release agent. Oiling the container is still going to be your best bet. You don't need more oil than what is necessary to put a shine on the bowl. Do you have any specific reason for not wanting to use ANY oil?

[Re: Help with Ankarsrum kneading, please! My Neapolitan dough won't relax.?2796](#)

JPB;

When the center section of the skin is too thin it does not provide the necessary insulating value between the hot deck and the sauce and other toppings....in short, heat from the deck passes right through the dough and is dissipated as steam during baking, this results in the crust never getting hot enough to provide maximum crispness. I would be looking at either of two options, 1) open to the same diameter but used more dough (test increasing dough weights), 2) open the same dough weight to a smaller diameter skin (test by opening the dough ball into skins of decreasing diameter (1-inch increments). This is the same reason why most super thin Neo pizzas do not retain their crispy bottom crust for more than a couple of minutes...if you're lucky.

[Re: Swimming upstream with NP hybrid dough?2797](#)

It looks to be a stamped steel pan about 1-inch deep with a well seasoned finish. You might look on the Internet for a rectangular baking sheet pan or check with Lloyd Pans at <lloydspans.com> for a similar pan with a non-stick black finish.

[Re: Pizza Pan?2798](#)

When looking at the picture of the slice it appears that the center of the crust is very dense while the edge/rim is open and porous. A dense crumb structure can result in tougher, more chewy mastication properties. If your dough formula doesn't include any oil you might see if the inclusion of 2% oil gives you something closer to what you're looking for...that dense crumb structure in the center of the pizza still concerns me though.

[Re: Swimming upstream with NP hybrid dough?2799](#)

When I make deep-dish pizzas I like to use a stone but I also place a screen on the stone upon which I place the pizza for baking. I've found it to be somewhat problematic controlling the bottom crust color when I bake deep-dish pizzas directly on a stone or steel due to the heat transfer properties when the pan is in direct contact with the stone/steel. My usual baking temperature for deep-dish

pizza is 450F. I've found that when I bake the pizzas in this manner the top and bottom are done at the same time, when I used to bake directly on the stone/steel I got a charred bottom crust all too often.

[Re: Steel Vs. Stone on A Deep Dish](#)**2800**

That would be my starting point for the base.

[Re: Sauce](#)**2801**

A small counter top oven like a small air impingement oven, or a small deck oven or possibly even a toaster oven would work well in this application. For display of the pizzas think of using something like a Hatco Pizza Display Cabinet with both temperature and humidity controls, and some good pictures too. Recon time will be around 1-minute or so.. If you want, you can also add a small amount of additional, fresh cheese to the top of the slice immediately before it goes into the oven for reheating.

[Re: Reheating slices in a food truck](#)**2802**

I have a hard time seeing where you can make and sell enough pizzas from this to make much of a profit BUT if you load the truck with ready made pizzas and refreshen/reheat/re-crisp the slices using a small deck oven (about all that will fit in there) you might have yourself a little gold mine.

[Re: Reheating slices in a food truck](#)**2803**

It'll give you a good flavored, slightly thick sauce base to build upon. The 7/11 will provide flavor while the Full Red Puree will provide extra body to the sauce, great for a deep-dish as is but will most likely need to be thinned a little for most other pizza applications.

[Re: Sauce](#)**2804**

I'm assuming we're talking about Saporito Super Heavy Pizza Sauce and Full Red Pizza Sauce as opposed to Full Red Extra Heavy Tomato Puree? That being the case I would probably consider going a little higher on the Full Red to restore some of the more pronounced flavor that will be lost from the Saporito, but all cards would be "off of the table" if you're adding any water to this the sauce. If you're adding any water go ahead and make the substitution and add less water (Full Red Sauce will be thinner than Saporito) so you will want to adjust the amount of water being added to give you a similar viscosity as you got with the 7/11 and Saporito blend.

[Re: Sauce](#)**2805**

If you use a "bulk" fermentation and then ball you will need to allow the dough balls to ferment again until the balls are sufficiently soft and extensible to be easily opened into skins. This could easily take 6-hours or more. Truth is, when making pizzas at home there is no difference between fermenting the dough in bulk or in individual balls, for this reason I firmly believe that it is much easier to just ball the dough right after mixing, place the dough balls into plastic bags or suitable containers (both methods previously discussed in great detail here) and then allow the dough to ferment for the desired length of time, then when you're ready to make your pizzas just turn the dough out of the bag or container onto a floured surface and immediately open the dough into a skin, dress and bake.

[Re: Beginner dough question](#)**2806**

Hummm, I always thought lasagna was a pasta dish??? Have I been wrong all these

years?

There are some arguments/disagreements that are just not worth the effort to participate in, in my books this is one of them. He is free to believe whatever he wants, I'd just leave it at that.

[Re: Deep dish not pizza?2807](#)

To summarize, we need to know specifically what issue you're having or seeing with your dough/pizza, your dough formula, flour brand/type/bag name, dough management procedure, type of oven, baking platform (screen, pan, disk, oven deck/hearth) and lastly what kind of cooler do you have (walk-in or reach-in). With this information we should be able to either identify the cause of the problem or give you some good direction to finding a resolution.

[Re: A year and half in pizza business. Need help.2808](#)

My formula is almost identical to GumbaWill's, after mixing I scale, round into balls, and allow to ferment at room temperature for at least 6-hours but occasionally it may go as long as 8-hours, or whenever we're ready to eat. Then I just plop it out of the bag onto a floured surface, open it into a skin, dress it and bake it at 500F. Nothing special, nothing to call the photographers in for, just fresh, hot pizza that everyone eats without any complaints, at least none that I can hear.

[Re: Same Day Dough2809](#)

When you prepare the dough for baking as Norcoscia outlines the crumb structure can be much more open and porous "airy", it will bake out better and it will eat like cotton candy. Here's a little trick you might want to try. Use a plastic shortening in the pan initially, it grips the dough making fitting the dough to the pan MUCH EASIER, then AFTER par-baking the crust, immediately remove it from the pan, wipe out the pan with a clean paper towel, add about an ounce or so of oil (I personally like to use peanut oil) to the pan and immediately place the crust back into the still warm pan, dress as desired and place back into the oven to finish baking. That oil will give the pizza a fried bottom crust which is significantly different from that of the crust you get when using a plastic fat to grease the pan. You COULD use oil in the pan right from the get go but then the dough is more problematic to fit to initially fit to the pan. This gives you the best of both worlds.

[Re: My first pan pizza!2810](#)

You probably don't want to use lecithin in a pizza dough. Lecithin is an emulsifier, it binds water and oil together. With an emulsifier added to the dough, the dough will exhibit a propensity to allow water released from the sauce and toppings during baking to enter into the dough where it can be difficult to bake out AND it also sets the stage for the development of a "dreaded gum line" just under the sauce. Without an emulsifier present the oil creates a barrier to water/moisture penetration/migration but with an emulsifier present you might say it exhibits an affinity to moisture.

[Re: High rate of oil in the dough2811](#)

Reduced fermentation tolerance means that the gluten forming proteins in a particular flour are not as resistant to the byproducts of fermentation (primarily acid attack) as other flours. A dough made using flour with a genetic characteristic of reduced fermentation tolerance will exhibit softer, more extensible and weaker characteristics with extended fermentation times than a dough made using a flour with good to excellent fermentation tolerance. Most, if not all U.S. flours intended for bakery application are milled from wheat varieties specifically selected for

exhibiting better than average tolerance to fermentation. All of the "00" flours that I've worked with over the years seem to do pretty well at 24-hours CF fermentation but begin to get "squirrely" at 48-hours CF. It's just the nature of the beast.

[Re: Swimming upstream with NP hybrid dough?2812](#)

QJ:

You're absolutely right...you've been reading too many of my posts. :)

I just recommended what I did as it represented a more minimal change from that what he was already doing but doing as you suggest would without a doubt solve any open issues and he would still have the option of allowing the dough to CF for 24 or more hours.

[Re: Dough was like a rubber band!2813](#)

All of the Stanislaus tomatoes are grown immediately around Modesto, California with but a single harvest for their entire yearly inventory. I had the honor of being invited to view their tomato harvest and processing a few years ago, it's quite an operation. Between gearing up, for the harvest, processing, and sanitation they then shut down the entire processing facility for maintenance and up-grading which takes about 3-months bringing them right back to the cusp of the next harvest.

[Re: 7/11, Stanislaus problems?2814](#)

I like that, my kinda humor ;D

After all, he was sorry for her "loss" :-D :-D

I've got to remember that.

[Re: Safety First2815](#)

Russ, you're not taking it....I'm bestowing it upon you! :chef: You pull this off, and I don't think you will have any problems in doing so, and you'll have rightfully earned it. I did it for 6 to 10 people, never 50 out in the woods.

For the toppings I just use a few cheap Styrofoam coolers with the ingredients packed on the bottom and a pound, or so, of dry ice on the top, be sure to place some crumpled paper between the dry ice and the ingredients and again over the top of the dry ice. Use one cooler for each days ingredients and tape closed to seal tightly, I have gotten up to 4-days of decent refrigeration in an unopened cooler, this is why you don't want to put everything into one single cooler.

While you're at it, make some extra dough, open it into skins, brush with melted butter and bake until very lightly browned, sprinkle with cinnamon and sugar mixture and put back into the oven for a few seconds, bring out and set aside to cool for a few minutes, while still warm drizzle with a powdered sugar-water icing, cut it and call it "dessert". For variety you can add streusel, chopped pecans, thin sliced apples (cored but not peeled), grapes cut in half, sliced strawberries or a few dabs of Ricotta cheese, any or all work well.....put those kids to work, they'll love the opportunity to help put the toppings on the pizzas! :)

[Re: camping pizza2816](#)

A dough/pizza skin is what keeps the sauce and toppings off of the oven deck, it's what, when baked, becomes the crust. When you round the dough you tighten the gluten structure, this is very evident after the dough has been allowed to ferment a period of time (like 72-hours), when you do this 3 to 4-hours is not enough time for the gluten structure to fully relax, that is why you are experiencing so much dough memory/snap-back when trying to open the dough into skins. We just recently had some discussion on this very topic here at Pizza Making.

[Re: Dough was like a rubber band!](#)2817

I used to do a presentation on "healthy pizza" where we did a 50% wheat crust, with no added fat, just regular white bread flour, whole wheat flour, salt, yeast, and water. For cheese we did a 50/50 blend of a tofu based cheese from Galaxy Nutritional Foods and regular low fat, part skim mozzarella cheese which gave us a 50% reduction in cholesterol without a reduction in the actual amount of "cheese" added. Toppings were poultry pepperoni, bison pepperoni, chicken, meat and fish analogs and vegetable toppings. This was a very "passable" pizza and an excellent alternative for those who couldn't otherwise eat a slice of pizza due to dietary restrictions.

[Re: High rate of oil in the dough](#)2818

What happened is that you balled it up 3 to 4-hours before "TRYING" to open the dough balls into skins. Let's change your procedure to a more user friendly one. After the 72-hour CF scale and ball the dough, place it back into the fridge to CF until the next day when you are ready to make your pizzas. Remove the dough balls from the fridge and allow to warm AT room temperature until the internal temperature of the dough reaches 60F, then with minimal handling, begin opening the dough into skins.

Let us know how this works for you.

[Re: Dough was like a rubber band!](#)2819

We did an analysis on commercial frozen pizzas a good number of years ago and we found that fat content of commercially made pizzas was quite a bit higher than that found in many chain and independent pizzerias.

Why you ask?

PEOPLE LIKE FAT, people buy things that appeal to them and satisfy them, frozen pizza companies are in the business of selling pizzas to make a profit, more pizzas sold = more \$\$\$\$.

How much fat did we find in those commercial crusts? The lowest was I believe 16% and all the way up to about 25% if I remember correctly. To put this in perspective, this is about the same fat content as found in many rich sweet doughs and is even in the realm of a croissant. Tell me people don't like sweet rolls and croissants :-D. I don't remember who it was anymore but someone was even making pizzas on what they called a "croissant" crust.

Granted, it does make a different type of crust, it makes for a very tender eating crust and if made as a thin crispy crust it will not be heavy, or dense at all, just consider a pie crust, about the same fat content, dry and crispy. And don't forget that your favorite club crackers will contain upwards of 8 to 10% fat, thin and crispy but made using only about 35% dough absorption.

As for healthy eating, that's a personal thing. For a lot of families pizza is the main entree of a meal and calories count for them, granted, they may not all be good calories, but calories are calories (9-calories per gram of fat, regardless of the type). For me, Yes, I do try to eat healthy so I find a crust that I like and then control the calories by specifying what toppings I want on my pizza, makes it taste better that way too. :)

[Re: High rate of oil in the dough](#)2820

Why sift the flour?

- 1) To remove flour beetles.
- 2) Remove flour beetle larvae (wormy flour).
- 3) Clumpy flour (Indian meal moth infestation in your flour, sifting removes the

larvae and the clumps)

4) Flour got wet and has clumped, sifting will remove the clumps but probably not a good idea to use the flour due to the potential for presence of aflatoxins due to fungi now growing in the flour.

If your flour is clean and relatively fresh there is no need to sift it unless the "recipe" being followed calls for volumetric portioning "sifted" flour.

Sifting of the flour will not impact air nuclei formation.

A dough docker is used to CONTROL bubbling on the top surface of a dough skin during baking, it is not used to aerate the dough in any manner. I've never seen a dough docker used on a finished (baked) crust of any kind.

[Re: To what point is the optimum for kneading pizza dough?2821](#)

Bamajj;

And they used to call me "Camp Mama", my friend, you put me to shame! :-D I would make some dough balls, place in plastic bags, and freeze without any prior fermentation. First day at camp site is set-up day, so no pizza. That night remove frozen dough balls from the cooler and place in an empty cooler where they will cold ferment over night and into the next day, remove from the cooler as needed to make the skins and dress for pizza (the skins, not the attire as this will be an informal affair) :-D. That night make a dough using a dry mix that you made at home (all ingredients except oil and water). Add the mix to a suitably sized bowl (large plastic bucket can work quite well, and it already has a fitted lid and is easy to transport and you can keep your pizza tools in it when it isn't filled with fermenting dough). Make a dish in the center of the dry mix and begin adding water while hand mixing, when the dough is completely formed stop mixing, lightly oil the sides of the bucket, loosely lid the bucket and set aside to ferment over night. After breakfast on the following day remove the dough from the bucket and knead on a lightly oiled plastic table cloth/covering (about \$3.00 at Walmart), pick a suitable color if you're so inclined, mine is red. Spring clamps work well to affix it to a table. Knead the dough a few times (don't get carried away), divide it into desired size pieces (eyeball it) this is a CAMPING TRIP, not a formal pizza party. Lightly oil each dough ball and get a few kids to help placing them into individual plastic bags, twist the open end into a pony tail and tuck it under the dough ball as you place it onto a sheet pan or other flat surface, mine is a piece of 1/2-inch Melmine laminate that serves double duty as a pizza cutting and serving table as the dough balls are removed. A 2 X 4-foot piece will cost you about \$10.00 at Menards. Allow the dough balls to ferment at ambient (hopefully in the shade), until you're ready to open them into skins, open the skins on that piece of Melmine laminate, dress and bake. Don't forget to bring extra dusting flour!

Dough Formula:

Flour: 100% (KABF or equivalent)

Salt: 2%

Sugar: 2%

IDY: 0.2%

Oil: 2% (this is portioned out using a measuring cup at the camp site)

Water: 60% (this is portioned out at the camp site)

Weigh all ingredients except for the oil and water together to make a single day's worth of dough..whatever that amount is.

Using a hand whisk blend together. You don't need to get carried away here either as this will be for a single dough.

Transfer to a plastic bag and close with a twist tie.

Repeat for as many days as you feel you might want to make pizzas on.

I bestow upon you my crown as "Camp Mama"....you will have truly earned the title! ;D

Have fun and send us some pics!

[Re: camping pizza](#)**2822**

Norcoscia is "spot-on" with his advice.

A par-baked crust is a crust that is baked either with or without sauce (typically about 1/2 of the sauce) and then removed from the pan and either held at room temperature for later use or immediately dressed and placed back into the oven to complete the baking process.

A pre-baked pizza is one which is completely baked on a raw dough, removed from the pan and allowed to cool for use at a later time but more commonly placed into a temperature/humidity controlled cabinet (like a Hatco cabinet) for use/sale by the slice. Pre-baked deep-dish pizzas DO NOT reheat very well at all, this is why they are almost always held in some type of a temperature/humidity controlled cabinet to keep them at serving (legal serving) temperature (minimum 140F).

All baked pizzas should be removed from the pan as quickly as possible after baking, failure to do so will result in moisture being trapped under the pizza resulting in a wet, soggy bottom crust...yummy!

[Re: My first pan pizza!](#)**2823**

Yes and no....allow me to explain. Yeast by itself cannot effectively leaven a dough, it must have a small air nuclei which is thus expanded into the cell structure we are accustomed to seeing in yeast leavened doughs. You are correct in that mixing and/or kneading the dough does incorporate air into the dough but it is not this air which creates the necessary nuclei, instead it is the air in the ingredients in the mixing bowl that provides the nuclei. Just make a dough sometime by just gently stirring the ingredients together without any kneading at all and you will see the development of the familiar cell structure. The ONLY way to mix a dough without this nuclei is to mix it under a strong vacuum which will pull all of the air out of the dough. There is a commercial mixing system that does this to some extent for making a finer crumb structure in pan bread, it's called the Tweedy Mixer or the Chorleywood Bread Making Process. Without the air nuclei the dough will just sit there as if it didn't contain any yeast at all, in the above mentioned bread making process a small amount of measured air is incorporated into the dough to develop a very small, fine cell structure desired by consumers in the U.K.

[Re: To what point is the optimum for kneading pizza dough?](#)**2824**

JPB;

Before doing anything else I would suggest incrementally increasing the dough absorption as this will allow the dough to open more during oven spring allowing for better bake-out. See, the issue here is that we don't know if we have achieved maximum bake-out yet or not. So what's recommended is for you to do some more test bakes (I know how much you hate to do that by the look of your great pizzas!) using both maybe 700F as your long, low temperature bake and 800F as your high temperature bake, see if you can achieve what you are looking for at either of these temperatures along with the increasing absorption. If you find that at some point the finished crust starts going the other way, getting softer and more chewy go back to just before where this started and that will be your optimum (not to be confused with maximum) dough absorption and baking conditions for that SPECIFIC dough formulation and dough management procedure. Now you are ready to start all over again using a new/different dough formula or I would

suggest just a different flour blend. In this case I think I would favor going with more of a weaker flour like the "00" flour in the flour blend. Reasoning being that the more extensible gluten structure will tend to promote more oven spring BUT keep in mind that "00" flours typically do not exhibit good fermentation tolerance and it will require a lower dough absorption so you will need to be looking at both of these aspects of your new dough during testing.

Now you're getting a taste of what the pizza side of my career has been like. It's like a never ending pizza party where you keep meeting new friends who you never knew you had. :chef:

[Re: Swimming upstream with NP hybrid dough?2825](#)

PB wheels;

IDY provides approximately 25% greater activity than ADY when used at equal levels. When substituting IDY for ADY just remember to reduce the amount of IDY by 25% for the same level of yeast performance that you got using the ADY.

[Re: My first pan pizza!2826](#)

We would need to know more about the dough, like the finished (mixed) dough temperature and the type of yeast you're using. The amount calculates out to 0.8% (very high for IDY, a bit high for ADY and a bit low for CY) With a high yeast level and a finished dough temperature much over 80F fermentation could progress at a pretty lively pace. Maybe that's what you were seeing? As for placing a pan on top of the proofed dough to keep it from over proofing or getting too thick during the baking process, it is possible but I don't recommend it and it will take some pretty serious holding force to keep a run away dough in check during the oven spring stage of baking. After par-baking the crust be sure to de-pan the crust and invert it onto a cooling screen/rack immediately upon removal from the oven. Inverting the crust helps to flatten the top out.

[Re: My first pan pizza!2827](#)

One that I remember which was related to pizza was a lady with long hair in a pony tail as she was preparing something in a bench top mixer her hair became entangled in the spinning agitator...you can paint the rest of the picture.

Another one happened in a wholesale bakery back in the 1950's, a large dough (most likely about 1,500-pounds in weight) was being ejected "kicked out" of the mixer by the mixer operator, the mixer helper saw that the dough was beginning to be pulled back into the mixer (this is common with horizontal mixers aka barrel mixers) so he stood in front of the dough trough positioned in front of the mixer to receive the dough, as he grabbed the dough to hold it from being pulled back in, the gluten won the fight and quickly pulled the dough back into the running mixer, with the dough being somewhat sticky/tacky the helper was unable to free himself from the grip of the dough and was pulled into the running mixer along with the dough. The outcome was fatal. Then in the early 70's, same scenario, but this time a person was standing in front of the mixer as the dough was being kicked-out, the dough was successfully discharged into the dough trough but a large piece of dough that was clinging to one of the agitator bars was flung out of the mixer and seriously hurt the individual when it struck him in the head. I've seen my fair share of them first hand too, and they're never pretty. One that we all need to be highly aware of happened to one of my technicians, while mixing dough in a Hobart A-200 mixer she was standing next to the mixer watching the dough being developed, then for no apparent reason she simply put her hand into the mixer...OUCH!

Investigation showed that when a person watches a dough being mixed (probably anything spinning) you develop what is called the "strobe" effect, this is where you

see the dough and the hook but don't visualize the movement. I had to test it for myself, yes it can and does happen! Bet you never saw that on a warning label on your dough mixer. I used to tell my group that every piece of equipment is like a predator, just waiting for you to make a single mistake, then it jumps out and grabs you, sometimes with dire consequences.

Moral of the story.....BE CAREFUL!

[**Re: Safety First**](#)**2828**

One of the things we used to do with our students was to make the dough one day (the dough was well under mixed and all but impossible to open into a skin) then the dough balls were cold fermented for 24-hours, brought to 50F and we opened the dough balls into skins so thin you could actually read through it...a beautiful example of full gluten development. It was a strong gluten film too as we would have five or six students form a circle with each grasping a part of the dough skin, they would gradually pull on the dough to continue opening it to see just how big they could get it. We were usually able to finesse the dough out to 30-inches or more...that was for a 12-ounce dough ball. Biochemical gluten development and fermentation do go hand in hand as it is the by products of the fermentation process which result in the biochemical gluten development. If you add a sourdough to the dough and then mix it to full gluten development we always got an extensible but sticky dough for our efforts.

Early on in our research we used to make a dough and divide it into individual dough balls and place them into the cooler in individual plastic bags, then we would begin removing dough balls at 8-hour intervals and opening them into skins taking care to open them all in a similar manner, we would note how the dough handles as well as the quality of the gluten film that we got from each dough ball. In the end we were able to watch the progression of biochemical gluten development and find the best time to achieve optimum gluten development for the product being made (normally either bread or pizza). Anything which impacts the fermentation rate of the dough will affect the time necessary to achieve a specific level of gluten development so the time will be specific to each dough formulation as well as dough management procedure employed. It's interesting to note that the dough will achieve full gluten development (this is where the gluten film is VERY THIN and CLEAR without any significant visual webbing seen in the film, once this has been achieved the gluten will start to become softer and more extensible (this can be a good thing when making pizza) until the dough finally becomes so soft and extensible (it is said to open itself) that it is difficult to handle. It was during these tests that we discovered that while the best bread is usually made when the gluten shows full development, the best pizzas are usually made after this point and closer to where the dough is becoming excessively soft and extensible. We also found out the hard way that dough which will be opened using a dough sheeter/roller should be closer to the full gluten development point than those which will be opened by hand or using a dough press/hot press, it has to do with the way the dough flows through the sheeting/reduction rolls, not enough development and the sheeter spits out chunks of dough rather than a sheeted dough mass, too much development and the dough is inconsistent in thickness or better yet it sticks to the sheeting/reduction rolls :(.

[**Re: To what point is the optimum for kneading pizza dough?**](#)**2829**

I agree that this is the best forum to discuss everything pizza and pizza related but every once in a while someone gets too worked up over whatever or is just having a bad day. I can and do appreciate the burning desire we all have to make a better or different kind of pizza or just learn more about it but at the same time whether

asking or answering a question or contributing in any manner it's important to consider how your communication will be perceived by others. I for one find it offensive when someone uses foul or offensive language/words in any context, even if it's part of their vernacular as you just know someone is going to take it wrong and think it's a personal attack or wrongly feel a level of hostility (especially with members who might have just recently joined us). In these rare instances I think a personal warning should be sent to the offender, then if after a couple of reminders they continue the offense this is when some kind of action would be justified.

[Re: Members opinion / feedback on how banning is currently implemented](#) **2830**

Wood bagel boards were banned a number of years ago but you can still find them occasionally and they would make a great liner for a plastic dough box.

There has been a fair amount of research done over the past few years on the anti microbial properties of wood (dough boxes, dough troughs, bagel boards, bench tops, etc.) and yes, it has been found to be safer than plastic which develops deep scratches and is all but impossible to clean/sanitize. Wood has the same problem but because of the anti microbial properties and because any microbes present tend to be the most predominant in the food/dough being made (typically some form of lactobacillus) there really isn't any problem....now, try to convince the food safety people of that.

[Re: Pizzeria Da Attilio dough in wooden boxes](#) **2831**

Looks good enough to eat! ^^^

[Re: I try and i Try.... And i Try!](#) **2832**

There are three ways to develop gluten, hand kneading, machine mixing and biochemically.

What Bill is referring to is basically biochemical gluten development where we combine the ingredients together just until we get a smooth dough but not to develop the gluten to any extent, then we allow the dough to ferment for a period of time (usually 24-hours or more) during which time the gluten is developed biochemically resulting in a very extensible gluten film, it is then folded (kneaded) a couple of times to redistribute the gas cells within the dough and mixing is considered to be completed. Unless you're making bread or just want to have arms like the village blacksmith kneading the dough by hand in an attempt to develop the gluten structure is not needed or even desirable in pizza dough production. In fact, after a world wide trip back in the 1970's during which I documented how bread was being made in developing countries I reassessed my whole view of hand kneading the dough for making bread too and instead of extensive hand kneading I developed a method where the dough was made by literally stirring the ingredients together and fermented for 4-hours, the dough was then turned out of the fermentation container and kneaded a few times until a smooth dough was achieved. Because of the biochemical gluten development this was very fast and easy to accomplish (like Bill said), we could then mould the dough into the desired shape(s) and finish by proofing and baking. I saw this procedure being followed almost exactly as shown when I visited a very large bakery in Romania. Mixing bowls were about 4-feet across and 3-feet deep, water went into the bowl, then salt, sugar and yeast (I know, bad idea), followed by the flour (90kg.), this was mixed by two men with what looked to be boat oars each about 4-feet in length, they mixed/stirred until the "dough" had the consistency of thick oatmeal, then they went to the next one and repeated the process (there were 60 bowls in all in that bakery), when they were finished "stirring" they removed the dough from the mixing bowl and loaded it onto a wagon that was transported to the kneading area

where several men would cut the dough into smaller size pieces, knead the dough for a few times and set it aside, then move on to another table and repeat the process. After they had chunked and kneaded the dough on five tables they returned to the first table, cut the dough into pieces for making beehive loaves, the pieces were loosely rounded and placed into prepared beehive baskets for final proofing, after proofing the dough was turned out from the baskets onto an oiled baking sheet and baked to a rich dark brown color. This was a continual process with truck loads of bagged flour arriving several times during the day. By the way, those two guys stirring the ingredients together.....not an ounce of fat between them, just muscle and sinew. Remember, this was communist Romania and everybody had a job....but not all jobs were easy. Point is, biochemical gluten development has been around for a very long time and it works quite well, especially if you want to have a well developed gluten film which is still very extensible and easy to work with. When the same level of gluten development is achieved through machine mixing you end up with a very tough, elastic gluten structure that is more difficult to work with unless long fermentation times are employed and you get something in between the two with hand kneading to full gluten development but like I said, you get quite a work out doing so.

[Re: To what point is the optimum for kneading pizza dough?2833](#)

Going to miss your posts but glad to see that you're sticking around. Keep us posted on what you're up to.

[Re: Norma2834](#)

Wooden dough boxes are wonderful for inoculating the dough with good bacteria. They were used in cracker production up until the early 60's then we had to get rid of the wood dough troughs and use steel troughs, when we did this the flavor of the crackers changed. We discovered the inoculation that was unknowingly taking place, replicated/cultured the bacteria and added it back to the dough as an ingredient, problem solved. Gotta love those wood dough boxes!

[Re: Pizzeria Da Attilio dough in wooden boxes2835](#)

three to four days on the outside, then you'll begin to detect some sourness...not a good thing :(when stored at refrigerated temperatures. Best to freeze as single use portions. This is not the best but it beats a sour sauce and it's about the best we can do to hold surplus sauce for an extended period of time. You do realize that the garlic you're adding to the sauce will catalyze the pectin in the tomato causing it to gel making tomato jelly? Best to add both garlic and onion (they both do this) directly to the pizza or if you want to add it to the sauce put it into a little water and microwave it until the water just begins to boil, this will denature the enzymes in the garlic/onion responsible for this dastardly deed and you won't need to worry about making tomato jelly.

[Re: Safe sauce storage2836](#)

I forgot to answer your last question, "How will the rolls baked in a pizza oven compare to those made in a commercial bakers oven?" If you're not a baker by skill level there will be a learning curve for you to learn how to make the rolls, but once mastered you will be able to make something acceptable which is probably OK for your application where a little individuality in the rolls, like our pizzas is accepted, and expected, by our customers. When the baker makes them he strives to have them all look alike and be as perfect as possible.

[Re: Baking sub rolls in a stone deck pizza oven?2837](#)

When I say to "bake off of the deck" I mean do not place the pans containing the dough directly onto the deck/hearth of the oven, instead, place a few steel rods between 8 and 12.5mm in diameter on top of the oven deck/hearth. Then place the pan of dough on top of the steel rods which will hold the pan up off of the deck creating an air gap/space between the oven deck/hearth and the bottom of the pan. This will allow the rolls to bake more uniformly. Breads and rolls bake differently from pizza. Pizza bakes from the bottom up, this is why we place the pizza directly onto the oven deck/hearth but breads and rolls bake more from the top down so we must keep the bottom of the pan up, off of the oven deck/hearth, if this is not done the rolls will be over baked on the bottom.

[**Re: Baking sub rolls in a stone deck pizza oven?2838**](#)

Because a par-baked crust will be re-freshened, means the same as baked a second time, you can use it up to 4-days after making it. Just store them at room temperature, I recommend penny stacking them in a suitable plastic bag and placing them into a dough box for storage. I do not recommend holding them more than four days due to the probability of mold growth on the crusts.

While some might advocate refrigerating the crusts I do not as refrigerated temperatures accelerate the rate at which the crusts stale and you are going to need to make sure the crusts are ALL uniformly at room temperature when you go to use them. If you cannot use the crusts that you've made in four days you're probably being a bit overly optimistic as to how many you're going to be selling.

:D

[**Re: Pan pizza2839**](#)

After mixing the dough allow it to ferment for 1-hour, then scale into 7-ounce/200-gram pieces, form each piece into a hot dog shape, place about 2-inches/50mm apart on an oiled/greased sheet pan, proof as directed, dock, spray with water, bake OFF OF THE DECK to get a more uniform bake. We used to place a few 3/8-inch diameter steel rods on the deck to hold the sheet pans off of the deck.

[**Re: Baking sub rolls in a stone deck pizza oven?2840**](#)

I know we have discussed at length the effects of the various dough ingredients on both the dough and

the finished crust but here it is in a nutshell:

Oil/fat/ shortening/lard/butter/margarine, etc.

They lubricate the dough for improved expansion properties during baking.

It helps to seal the cell structure to better retain leavening gas and water vapor for improved oven spring

It helps to reduce the migration of moisture from the top of the pizza into the crust.

It can provide a flavor.

It will help to retain those aromas lost during baking to provide a more rounded flavor in the finished crust.

It is known as a "tenderizer" as such it promotes a more tender eating finished crust (less chewy). Compare regular and fat free tortillas to see this first hand).

It can help to promote crust color too, not so much as a true color shift but a change in the hue of the crust.

It can also affect the mastication properties of the crust which can have a great impact upon how much or why someone likes a product.

It satisfies the "human fat gene"...people like FAT. This is why processed foods are high in fat. This is also why "fat free" was never popular.

There are two "optional" ingredients in pizza dough, they are: fat and sugar. Do you

need them in a pizza dough, of course not, flour, water, salt and leavening are all that's needed, but sometimes we need to modify the dough for specific purposes so we use fat or sugar. Sugar is used for crust color development, flavor and crumb color (depending upon the type of sugar used), and as a nutrient for the yeast. Any residual sugar remaining in the dough will be concentrated and act as a humectant to pull moisture out of the air and from the top of the pizza potentially impacting the crispiness of the finished crust.

[Re: making dough without oil?2841](#)

After proofing the rolls (you will need some type of temperature/humidity controlled cabinet (80% R.H. and 95F) the rolls are given three to four French cuts (diagonal cuts) across the top as a form of docking (they're actually called "docking cuts") which allows the individual rolls to expand during baking without tearing apart or bursting. Steam in the oven keeps the crust cool to allow for expansion (oven spring) but you can address this by spraying the rolls with water just prior to baking. Bake at 425 to 450F for about 12-minutes +/- . Immediately after baking remove the rolls from the pan and place onto a cooling rack, then while the rolls are still hot brush with melted butter. Rolls are ready to use when cool. They are best kept in a sealed plastic bag at room temperature. They will keep for up to 4-days. NOTE: If you will not be re-freshening the rolls at the time of use I suggest using them on the same day they're baked. Hoagie buns will typically contain 6 to 8% fat. The reason for the high fat level is to prevent moisture migration into the roll when it is made into a sandwich and also to provide the desired tenderness. If you want to have a more chewy roll reduce the total fat to 2%.

As you can see, these are a lot of work and might require equipment which you don't have or have room for, this is why so many stores opt to have them made for them by a local bakery.

[Re: Baking sub rolls in a stone deck pizza oven?2842](#)

When making a pan pizza here is the basic procedure that I like to use; Use your favorite dough formula but increase the yeast level to 0.4% IDY as this will significantly reduce the time required to fit the dough to the pan as well as the final proofing time.

Use the dough at 48-hours for best results.

I like to use a dough loading factor of 0.124 for my dough ball weights.

After removing the dough balls from the fridge allow them to warm to 60 to 65F. Prepare the pan by either greasing with butter, lard, Crisco or butter flavored Crisco. The procedure is a little different if you want to use oil.

Place the dough ball into the pan and using your fingers push the dough out to fit the pan. If you want a flatter crust use a rolling/pastry pin to open the dough ball so it JUST fits into the pan.

Cover the pan and allow the dough to rise in the pan for 45-minutes, then press it out again, trying to keep it even. If you want to have a thin vertical edge (similar to a Chicago style pan pizza) pull the dough up onto the sides of the pan.

Allow the dough to rise in the pan a second time for about 70-minutes (time will vary depending upon how thick you want the finished crust to be)

You are then ready to dress the dough and bake (450 to 475F) until crust is browned.

If you want to par-bake the crusts open the dough balls using a rolling/pastry pin and carefully place it into the pan, set aside to proof for 45-minutes, then press out to completely fit the dough to the pan if necessary.

Allow the dough to rise in the pan again for 30 to 45-minutes, then bake at 400F

JUST until the dough is completely set....DO NOT OVER BAKE.

Immediately upon removal from the oven de-pan the crust and cool it inverted on a wire rack or pizza screen.

To use your par-baked crust, lightly brush with oil, place back into the baking pan with a little oil in the pan, dress the crust and bake at 475F just until the top of the pizza is done (baking on a rack or screen is preferable to baking on a stone/steel).

If you want to use oil in the pan for a fresh baked thick crust pan pizza you will need to open the dough ball using a rolling/pastry pin to a size just a little larger than the pan and then place the skin into the pan. It should completely fit the pan. Set the panned dough aside to proof for 30 to 45-minutes and re-fit the dough to the pan if necessary by gently pushing the dough with your fingers, allow to proof for another 45-minutes before dressing and baking.

If you want to fit the dough to the pan using your hands with an oiled pan place the dough ball on a work surface and open to fit the pan, place the opened skin into the pan and set aside to rest for 1-hour, then re-fit the dough to the pan, set aside to proof again but this time for 30 to 45-minutes, re-fit the dough to the pan if necessary, then dress and bake as directed above.

Done right the crust will be 1/2-inch or more in thickness and have a light, tender eating characteristic. I've found that the best flour for this type of pizza is one with about 12 to 12.8% protein content and 58 to 60% absorption. Your deep-dish pans should be dark colored and at least 1.5-inches deep.

[Re: Pan pizza](#)**2843**

Yep, 120F is too hot.

[Re: Can someone toss me a recipe with a 1/4" thick base for 16"](#)**2844**

Like I said...."talking point"

The Dough Doctor

[Re: PMQ Article: Favorite Pizza Styles/Crusts](#)**2845**

Nick;

That's a lot of 100L diastatic malt powder, but to your question, malt powder has a decided tendency to want to "pill" when it contacts water, because of this the best way to add it is to simply dry blend it into the flour with a few strokes of a hand whisk.

[Re: Another stupid question from Nick At Nite..er I mean Nick57.](#)**2846**

We covered a lot of this in some recent posts here but in general, if your "bulk" dough is for only two or three pizzas there is little if any difference between bulk and ball cold fermentation...totally different story if we are talking about bulk dough weight of over 1Kg.

Bulk CF, then scale, ball and CF = just more CF.

Bulk CF, then allow to warm to at least 50F, scale, ball and CF = reactivation of fermentation process so dough will receive more fermentation in the end.

[Re: CF bulk and CF balls](#)**2847**

Since you are using ADY you must pre activate it by suspending it in about 5 times its weight of warm (100 to 105F) water for about 10-minutes, then add the activated yeast suspension to the dough water and begin mixing. Amount of ADY to use will be between 0.5 and 0.6%.

[Re: Can someone toss me a recipe with a 1/4" thick base for 16"](#)**2848**

Within reason, the thicker the stone the better. A thicker stone allows for a more consistent bake. On the down side it takes longer to preheat. Some of the best commercial wood and coal fired ovens I've worked with have stones as much as 6-inches (15cm) thick. While some of the best commercial deck ovens have decks that are 1 to 1.5-inches thick (2.5 to 4cm approx.) thick.

[Re: Have you ever used stones thicker than 1½ ?2849](#)

If you're machine mixing the IDY should be about 0.375 to 0.4% and it should be added dry right to the flour. If you're hand mixing suspend it in a small amount of 95F (use a thermometer) water and activated for about 5-minutes prior to addition to the dough water. As for scaling weight for a 16-inch pizza approximately what are you looking for in crust thickness? Most of the time I'm looking for a crust with a finished thickness of about 3/16-inch thick which equates to a dough loading of about 0.106 (ounces of dough per square inch of surface area) or 21.3-ounces/605-grams. Your present 770-gram weight should be plenty to provide a good, thick finished crust if properly handled. As indicated your yeast/IDY level is much too low for this type of crust and I would also suggest that you consider baking the pizza on a solid, dark colored pan and allowing the dough to rise for a period of time prior to dressing and baking. I can't say how long to allow the dough to proof/rise for as there are just too many yet unknown variables but I would suggest starting with 30-minutes and then again at 45 and 60-minutes. This should give you the direction needed to zero in on the best time needed to achieve your end goal.

[Re: Can someone toss me a recipe with a 1/4" thick base for 16"2850](#)

Letting the dough warm to at least 50F helps a lot with opening the dough into skins.

[Re: CF bulk and CF balls2851](#)

Rutgers is a staple here in KS for us, we grow it every year. Not big (about the size of a baseball), but good yields and firm flesh with a great flavor if picked ripe. We also grow some Jet Star too but it doesn't yield as well for us.

[Re: Tomato choice: Rutgers or celebrity?2852](#)

Try using a stronger bread type flour such as Pillsbury Bread Flour (available at many supermarkets) or KABF, adjust the yeast level to 0.05% IDY and go up from there if necessary.

[Re: I am trying to achieve a 24 hr. RTF and something's wrong.2853](#)

Your taste buds? :-D

The only REAL test would be for you to evaluate both side by side under a fully prepared pizza using a triangular test where two like and one unlike sample are presented and the subject is asked to identify the odd (unlike) sample. This is repeated three times. If the unlike sample is accurately identified each time we say that there is a decided difference between the samples but if it is identified accurately two of the three times we say that there is potentially a difference and if it is identified accurately only once there is no significant difference. This is how we used to sort out ingredients with a potential impact upon flavor or aroma.

[Re: Effect of sugar on crust flavor2854](#)

The trend with whole-wheat flour today is to mill the bran to a finer particle size before adding it back to the flour stream. The good news is that it speeds up the rate of hydration a bit but the bad news is that people complain that it doesn't look like whole-wheat flour as they're accustomed to the coarser particle size associated

with stone-ground whole-wheat flour (not actually stone ground, just a particle size reference). Whole white wheat flour are following this same trend, in fact, most commercial premium whole-wheat breads are made using a fine ground whole white wheat flour as it provides an improved flavor over the more common whole-wheat flours made from hard red wheat varieties.

[Re: Percentages of Flour added to white?2855](#)

Using the bran flakes is indeed a good way to get an idea of how much whole wheat flour is being used.

[Re: Percentages of Flour added to white?2856](#)

15-minutes is a long mixing time unless you are doing all of the mixing in low/1st. speed. Please let me know all you can about your mixer and how you are mixing the dough. A video would help greatly.

[Re: Advice. 2857](#)

It sure does but the total mixing time is only in the 60 to 75-seconds range. A similar type of mixer that you might know of is the Robot Coupe mixer.

[Re: Why does my fresh dough do not bubble ?2858](#)

Mixing is not the issue here, it's fermentation. When using the Caputo Blue 00 flour I've used 60% absorption and 24-hours room temperature (70F) fermentation all in ball form and the dough just about opens by itself, maybe a little easier than I like, so if you find that to be an issue just begin working with lower dough absorption values. I've also used 36-hours cold fermentation with about 90-minutes at room temperature prior to opening, again all in ball form, no bulk.

[Re: Help with Ankarsrum kneading, please! My Neapolitan dough won't relax.2859](#)

They really don't reheat very well in a commercial application because everything is enveloped in dough which is an excellent insulator and by law you're going to need to reheat to an internal temperature of 160F minimum (165F actual). We have done calzones where they are fresh bake and held under a warmer to allow them to be served over a longer period of time and then given a quick pass through the oven to dry the crust prior to serving if that helps any. We did this for a store in Newark, N.J. where we did a killer business serving breakfast calzones to commuters (rail station literally right across the street). These were fresh made, held under a heat lamp to keep them warm, and placed into a paper sleeve and sold with a cup of coffee as a breakfast special. These were smaller individual serving calzones and while I hate to say this, overall quality had to take a back seat to convenience (sorta like delivery pizza). How successful was it? They had to purchase a 70-inch XLT air impingement oven just to keep up with the demand. I suppose you could hold the larger dinner size calzones in a temperature/humidity controlled box (Hatco) at 150F (145F is the minimum serving temperature IF the product has not cooled under 145F) and then refreshen it with a pass through the oven just before serving. This should expand the window for sales to around 2-hours, or so. The same would hold true for stromboli.

[Re: Stromboli and/or Calzones2860](#)

Peter;

You're absolutely correct. Tests performed back in the 1960's showed that it took a minimum of 4-minutes of machine mixing time to thoroughly disperse the IDY (5-minutes is usually recommended as a precautionary measure). Even when using the VCM (vertical cutter mixer) with a mixing speed of 1750 r.p.m. (variable with

different models, but all at or above 1700 r.p.m.) it was found necessary to first suspend the IDY prior to addition to the mixer.

[Re: Why does my fresh dough do not bubble ?](#)**2861**

He who holds the pizza holds all the aces when it comes to kids. Try to get them involved in making the pizzas too, we used to make it a family effort when the kids were small and they absolutely loved it. Their best part was that we let them each make their own pizza with their favorite toppings. Our youngest son is now 48 and the oldest is 53 and dad still makes pizza for them...it's their favorite treat, but now the order has grown from three pizzas to a minimum of five plus calzones (both boys think of calzones as an appetizer.....go figure!) and desert pizzas too, or if we don't have desert pizza we will have one of my specialty cakes :chef: it's really not much work though as the grand kids like to roll up their sleeves and practice their pizza making skills too, that is until the pizzas begin coming out of the oven, at which point I'm on my own. Best part of it? Both boys still talk about some of our more memorable cooking and baking episodes.

[Re: Neapolitan dough at 9000'](#)**2862**

Yes, that is the recommended procedure when doughs are mixed by hand. The temperature of the water in which the IDY is dispersed should be a measured 95F. Temperatures that are as little as 5F off in either direction will impact the way the yeast ferments.

[Re: Why does my fresh dough do not bubble ?](#)**2863**

Another thing to keep in mind is that P.H. used to use a lot of tomato paste in their sauce which is why it had that very dark color.

[Re: Help with making a better sauce?](#)**2864**

Considering the high dough absorption I don't think the dough is over fermented yet, slack doughs do collapse under their own weight a lot sooner than a lower absorption dough will, From the looks of the dough I would estimate that it is at the first full rise, this is the point in dough fermentation there the dough rises and then begins to drop (first full rise), the time required for the first full rise is typically about 80% of the total dough fermentation for making bread or about 50% when making pizza, assuming a good, strong flour is being used which would be the case for a N.Y. style pizza, but then we all know about that word "ASSUME". In any case, a dough which has been fermented to anything close to first full rise will exhibit sticky characteristics when first removed from the bowl.

[Re: very sticky dough](#)**2865**

Actually, fresh yeast/compressed yeast/CY does not need to be activated/hydrated, plus the addition of the honey and sugar is most likely suppressing the yeast activity for a period of time (assuming your yeast is fresh and in good condition, which a lot of times is a great unknown when using CY as it is highly perishable). Like bigMoose said, IDY is by far the best and easiest yeast to use, no need to activate, just add it right along with the dry flour and you're good to go.

[Re: Why does my fresh dough do not bubble ?](#)**2866**

Two things:

- 1) Your dough absorption is 70% which is probably pushing the upper limits for your flour so I'd suggest reducing it to 62% (682-grams).
- 2) What your picture shows is a fully fermented dough. Without much more information on how you are handling the dough as well as temperatures employed I

can't say if the amount of fermentation is excessive or not but it doesn't appear to have turned into "soup" so I'm assuming fermentation is OK. With that said, fermented dough as shown is always going to be sticky...it's the nature of the beast. Here's what to do. First, lightly oil the bowl that you are fermenting the dough in (this will make it easier to turn the dough out of the container). Turn the dough out of the container and very lightly dust the dough and then divide it into desired weight pieces, form each piece into a ball and handle normally from there. Remember, it will take at least 6-hours of additional fermentation time before the dough balls will be ready to be opened into skins.

[Re: very sticky dough](#)**2867**

Power flour comes in at 13.5% protein content while the Mondako is at 12% protein content. As N.Y. type pizzas are typically made using high protein flours such as All Trumps (14.5% protein content) I would go with the Power flour. When deep-dish pizzas are made from excessively high protein flour the result is usually a very tough, chewy eating characteristic unless very long dough fermentation times are employed. When we did the AIB pizza seminars we found that flour with 12 to 12.6% protein content was a very good and acceptable "all around" flour for making both thin crust (including N.Y. style) and thick crust/deep-dish pizzas without the need to inventory two different flours.

[Re: Grain Craft - Power Flour vs Mondako](#)**2868**

The 24-hour fermentation period at room temperature will effectively build acid content of the dough which will effectively mellow the flour protein making the dough quite soft and extensible.

[Re: Percentages of Flour added to white?](#)**2869**

Surveys, like polls should ALWAYS be taken with a grain of salt. The results of either can be manipulated (on purpose or unintentionally) by the questions asked when conducting the poll/survey and the very people selected to participate in the poll/survey can have a tremendous impact upon the outcome too. Polls and surveys are useful when done with a specific objective (done by a major frozen pizza manufacturer to determine the most popular frozen pizza in Houston, TX...for example), but aside from that, in my opinion they make for talking points, that's all, and it's my guess that that's what PMQ was trying to achieve.

[Re: PMQ Article: Favorite Pizza Styles/Crusts](#)**2870**

The only reason for wanting the dough balls to retain their "ball" shape is when placing them into plastic dough boxes for storage in the cooler (think pizzeria), aside from that there is no valid reason why the dough has to retain a ball like shape. So what if it flattens out a bit? You're going to do more of the same when you form it into a skin. If the dough is properly fermented the dough will be sufficiently extensible so that even if it is a little out of round it will still be very easy to form a round skin from it. We do it every day at pizzerias across the country where we need to dig/scrape a dough ball out of a dough box (which results in a mis-shapen dough ball) and then open it into a round pizza skin.

Placing the dough into a larger container will allow for significant head space between the dough and the top of the container which can lead to condensation forming in the container resulting in a wet or sticky dough...there is no head space when a plastic bag is used and you don't need to place the dough in the fridge uncovered for several hours to allow for consistent cooling of the dough prior to lidding the container.

How to handle the kids: Look kids, we all like pizza...right? In order to make pizza

daddy needs to make his dough and if you put something on top of the dough balls he may not be able to make the pizza crusts from his dough and without the crusts there can be no pizza, so be careful around the bags of pizza dough. Case solved. Just moving the dough balls won't hurt them, neither will pushing anything up against them cause any harm either. If you ABSOLUTELY must put the bagged dough balls into something, after they have been in the fridge for at least 3-hours place them into plastic tubs (we use the plastic tubs that whipped topping comes in) but DO NOT apply the lid. When we go to a friend's home to make pizza this is how we transport the dough balls....works great. :)

[Re: Neapolitan dough at 9000](#)**2871**

When you buy a dough docker just make sure you get one with flat/blunt docking pins. The Heavy Duty Plastic Roller Docker # DD5274 or DD5705 at American Metalcraft <www.amnow.com> are good examples of dough dockers that really work well. You might be able to find them at a local restaurant supply store or online too.

[Re: Dough not very smooth, small bubbles everywhere](#)**2872**

It all depends upon how much fermentation the dough will be getting.

[Re: Percentages of Flour added to white?](#)**2873**

That being the case there might be more rye flour in the dough than what the pictures showed. I would reverse the percentages of rye and whole-wheat flour from my original recommendation. With 20% rye flour there are three issues to contend with regarding dough absorption. One is that rye flour has a high absorption value by itself (70% on average) and second, it has little gluten forming protein so it dilutes the gluten forming protein in your white flour making for a weaker dough structure and three, rye flour produces a sticky dough characteristic (an inherent characteristic of rye flour), this is why getting the dough absorption correct on a rye based dough is a bit tricky...HECK! It's the most difficult of all the doughs to hit the absorption correctly on. In the baking industry we use VWG to improve the handling properties of doughs with rye flour (15% of the weight of the rye flour is a good starting point if you want to add VWG to the dough). If you opt not to add VWG I would suggest starting at 72% absorption and cautiously working up from there if deemed necessary. Table stretching the dough might be a better option in this case than hand tossing or hand slapping when opening the dough balls.

[Re: Percentages of Flour added to white?](#)**2874**

JPB;

You bring up a good point there. I've seen a lot of pizzerias where the "bubble popper" is the tool of the day. Additionally, correct docking of the dough can go a long ways in addressing unwanted bubbles.

[Re: Dough not very smooth, small bubbles everywhere](#)**2875**

0.5% ADY is equivalent to 1% compressed yeast (CY) which is waaayy too much yeast for a 24-hour room temperature fermentation period especially with Caputo "00" flour which isn't especially fond of long fermentation times. Using Caputo "00" flour the longest I have been able to ferment it is 24-hours CF, at 48-hours it was deemed to be marginally usable. I would suggest starting at 0.1% and work up from there. You can always give a dough extra fermentation time but it's difficult to take it away.

No yeast? Sure no "added" yeast. A sourdough leavened dough might be said to

have no yeast, no added yeast that is, but within the sourdough itself you have both yeast and bacterial fermentation taking place which will leaven the dough quite nicely. I only wish I had a dime for every time someone said we don't use any sugar in our dough, but strangely, there is honey in it....guess honey doesn't qualify as a form of "sugar" even though its constituent ingredients are fructose and dextrose. As for your question on mixing, the optimum mixing time for most pizza doughs appears to be JUST enough mixing to allow the dough to be balled without the skin tearing as the ball is formed, this is assuming you're not trying to make your dough balls tighter than a golf ball is wound. You can see the change in the mixing bowl during mixing as the dough will begin to stretch (sheet is the correct term) thus reflecting light creating what appears to be a brighter colored dough with a satiny appearance. If your mixer has a "J" hook you may never be able to see this due to the poor mixing action of the "J" hook.

[Re: Dough FAIL!!!!](#)**2876**

Scott;

You have never smelled a fresh baked, still hot angel food cake right out of the oven. Egg albumen takes no back seat to VWG, but both change considerably upon cooling when used in correct context. When I worked in production I ran a cake line for several months and I can still smell those things, but once they're cooled.....it's "game-on" ! ;D

Denaturing of proteins can create some pretty disgusting aromatic fragrances.

[Re: Results of my Diastatic Malt Powder Enzyme Tests](#)**2877**

I would suggest replacing 30% of the total white flour with a blend of 20% whole wheat flour and 10% dark rye flour and benchmark from there. Rye flour doesn't contribute much of a brown color to the dough or finished crust, instead it is best described as a "muddy" grayish brown color, this is why caramel coloring is so widely used in rye breads, now you know the "real" reason why rye bread/dough has a brown color. Most of the color you're seeing is most likely from the whole wheat flour, hence the greater amount of whole wheat flour. There appears to be particles in the dough which could be from the use of a "stone ground" (an expression used today to describe a coarse ground flour) whole-wheat flour or it might be due to the use of a pumpernickel rye flour but I can't tell from a photograph which one it might be.

Remember that the use of these flours will INCREASE the dough absorption. If the dough is not tacky when removed from the mixer your absorption is most likely too low.

[Re: Percentages of Flour added to white?](#)**2878**

Not a bad start! Not bad at all! ^^^

Develop your proficiency by tuning the dough and toppings and you'll be ready to rock and roll when you get your oven back!

Try my favorite sauce...nothing more than a lightly oiled skin to which thin slices of fresh, ripe tomato are added, flavor with fresh basil leaves and top with some fresh mozzarella cheese. If you can't get the fresh, ripe tomatoes just open a can of stewed plum tomatoes, tear apart by hand, drain well and place pieces over the lightly oiled skin along with the fresh basil leaves then add the mozzarella and a sprinkling of Parmesan cheese.

OK, so why the generic stewed plum tomatoes? Saving the good stuff for when you get your oven back. :chef:

[Re: Neapolitan dough at 9000'](#)**2879**

You can get some very good oven spring with a high absorption dough IF you have the oven temperature to support it. I think lowering the temperature might be the wrong direction to go. Lower temperature = less and slower steam generation during those first few critical seconds in the oven which equates to less oven spring which in turn results in a less porous crumb structure whichwell you see where this is going :-D

Keep us posted on your progress.

[Re: Swimming upstream with NP hybrid dough?2880](#)

Judith;

In addition to what Qwerty Juan pointed out regarding your dough weights the following should be added to the previous formulation which I converted into bakers percent for you.

Yeast (IDY): 1.56%

Salt: 1.56%

Sugar: 1.56%

OK, let's look at it now.

The total dough absorption is 48.82% which is about right for a thin crispy type of crust which has a dough loading of about 0.08845-ounces per square inch of surface area. By this calculation your 14-inch pizzas are heavy for a formulation of this type. Your 14-inch pizza should have a dough weight of 13.6-ounces (13.5-ounces) and the 16-inch should have a dough weight of 17.7-ounces (17.5-ounces). The amount of IDY is pretty high at 1.56% especially in view of the 5-day CF. More typically I would expect to see it down around 0.1 to 0.2% assuming a finished dough temperature in the 70 to 75F range (what is your finished dough temperature?) (what is your dough management procedure?). Knowing these would help me to nail down the yeast level a little better.

The sugar level at 1.56% is OK but normally for this type of dough we don't use any sugar which allows the pizza to be baked longer to help develop the crispy characteristic this type of dough is formulated for, but depending upon the finished dough temperature and how the dough is managed it might be an important aspect in yeast survival over the 5-day CF period?

Assuming you're opening the dough balls using a dough sheeter/roller and docking the opened skins?

Just out of curiosity, is the 14-inch pizza more of a "problem child" than the 16-inch pizza? I ask this because it is the 14-inch pizza that is heavy for its size while the 16-inch pizza is about right.

[Re: NEED HELP WITH MY PIZZA DOUGH2881](#)

Some of the added ingredients in our flours are measured in "ppm" (parts per million). These include such things as potassium bromate, ascorbic acid and azodicarbonamide.

[Re: Results of my Diastatic Malt Powder Enzyme Tests2882](#)

JPB;

I'm guessing that when you reduced the dough absorption the dough became less fluid during those first few critical seconds in the oven when oven spring occurs. Before getting too far out on the limb I'd suggest going in just the opposite direction...go up in dough absorption, that should give you an improvement in oven spring which in turn will result in greater crust porosity resulting in a crispier finished crust characteristic. How much should you increase the dough absorption

to? I'd suggest increasing it as high as you can while still retaining ability to handle the dough. This judgement should be passed only at the time you are actually opening the dough into a skin. You may also find that making an autolyze using all of the flour and all of the water may help with high absorption while retaining handling properties of the dough. It wouldn't surprise me if you are able to reach 70% absorption. Let me know where this direction takes you.

[Re: Swimming upstream with NP hybrid dough?2883](#)

The amount of ADY is higher than what I personally use too. It calculates out at 0.92% which is equivalent to almost 2% compressed yeast. Unless I'm making an emergency dough for my pizzas I seldom ever use more than 0.5% ADY, comparable to 1% CY. Combined with dough temperature? this could also contribute to a somewhat gassy dough with large bubbles.

Now I'm two cents poorer.

[Re: Dough not very smooth, small bubbles everywhere2884](#)

Craig is "spot-on". The acid in the SD weakens/breaks down the gluten forming proteins in the flour much like marinating a tough cut of beef in beer or wine will help to tenderize it. If you look very carefully at the IDY label you may find ascorbic acid as an added ingredient to the IDY. While AA is used in the baking industry as an oxidant to strengthen dough in this specific case it is added to the dough in an amount calculated to address only the small amount of dough softening which MIGHT be noticed with the IDY. This slight dough softening results from the presence of dead yeast cells within the IDY (yes, some of the yeast cells are killed during normal processing) and these dead yeast cells release their glutathione into the dough (glutathione is very much like L-cysteine hydrochloride/PZ-44). The AA added negates this slight softening effect. Dead yeast is also used in products where a cleaner label is desired than which is possible with L-cysteine, this is because since all yeast ends up dead (thanks to the oven) it is allowed to be lumped right in with the live yeast on the label, in short, you can add a reducing agent without the need to show it individually on the label whereas L-cysteine must be individually shown on the label. By the way, both glutathione and L-cysteine are amino acids (protein building blocks), there is nothing to fear from either but the name.....kinda scary to some.

Tom Lehmann

[Re: IDY vs Sourdough2885](#)

By law, all flour sold in the United States must be labeled with the constituent ingredients, malted flour will typically show "malted barley flour" or "fungal amylase" as an ingredient. The Falling Number value of unmalted flour is carefully controlled through the selection of the wheat used in milling the flour. Wheat that has sprouted in the field will have a very low FN value (over malted), since you can't get the amylase activity out of the flour a sprouted flour is normally used for what is referred to as an "industrial flour", well drilling paste is a good example of this, but in some cases it can be blended with good, sound wheat to provide a flour with the desired FN value so what you end up with is a flour which is "natural" but with no additives and it still has decent baking performance characteristics for the baker desiring such a flour. When we buy organic flour this is a little different in that the wheat has to be certified as organic and no additives are typically added, in this case the flour will be completely unmalted and have a high FN value, but it can be malted if the sprouted barley flour is certified as "organic", in which case the malted barley flour will be shown as a constituent ingredient. With the growing popularity of "00" type flours millers have taken to producing specific flours

without any type of malt (cereal or fungal amylase) added to the flour, these flours are commonly referred to as being "untreated".

[**Re: Results of my Diastatic Malt Powder Enzyme Tests2886**](#)

What is your confirmed baking temperature?

[**Re: Uk- Lincat 630-2 oven2887**](#)

Have you tried FINE corn meal? The larger particle size slows the hydration rate substantially over that of flour so it allows for a longer peel time, plus it acts like little ball bearings under the skin to facilitate peeling the pizza onto the steel baking plate. It will also add another dimension of flavor and crispiness to the baked crust. Just be sure to use fine corn meal as anything else will be gritty.

[**Re: Workflow preparing multiple pizzas before baking2888**](#)

Craig;

For some reason amylase and protease enzymes seem to go hand in hand, meaning where you find one you will typically find the other. Ingredient manufacturers have really done their home work in trying to minimize one over the other so if you have an amylase preparation the protease is really minimized and if you have a protease preparation the amylase is really well minimized. This is important as the commercial baking industry (the main user of these ingredients) wants ingredients with ONLY very specific effects upon their doughs and because there is a greater need for amylase than protease in the industry the work has been really concentrated on getting rid of the protease contamination (minimizing it). The method used for protein determination is the Kjeldahl Test, a method by which the protein is broken down and the nitrogen released is measured and multiplied by a factor of 5.7. I don't remember the entire procedure anymore but if you go to the AACC (American Association of Cereal Chemists) web site you should be able to find it or possibly just Google the Kjeldahl Test and or AACC. This is a slow, time consuming and somewhat dangerous test as the technician is dealing with flasks of boiling acid at face level, but it is still considered the most accurate. A great percentage of protein measurements today are based in NIR measured protein level which is fast, easy and with essentially no danger associated with it. In both of these cases "protein is protein" meaning that only TOTAL protein is being measured not just the two gluten forming proteins glutenin and gliadin, the only way to isolate these two proteins and measure their amounts is to first mix the flour in water causing the glutenin and gliadin to bind resulting in what we call "glutin" and then, using ice cold water, wash the remaining materials away so what you are left with is a relatively pure wet gluten ball.

I think you may have the "ash" procedure confused with the protein procedure. When the ash content is measured the flour is burned in a Muffle Furnace leaving behind an ash residue which is measured and reported as "ash content". This is also an AACC procedure if you want to learn more about it.

[**Re: Results of my Diastatic Malt Powder Enzyme Tests2889**](#)

Amylase is an enzyme which hydrolyzes only starch. Native (intact) starch granules do not absorb water, only the starch granules which are damaged through the milling process are capable of absorbing water before being heated to the gelatinization point (140 to 180F+/-). The conversion of damaged starch to sugar is responsible for the noted stickiness and the slacked dough consistency resulted when the starch was hydrolyzed and gave up its water holding ability. The resulting simple sugars were responsible for the darker color of the gluten after drying. As there is very little proteolytic activity present in the malt there would be little or no

impact upon the gluten forming proteins. Washing gluten is a fairly imprecise technique, though it can be relatively accurate when done by a skilled technician. This is why we use the Glutamic Gluten Washing Machine today for all of our wet and dry gluten assays. While we typically report protein as an indication of flour strength, when protein is reported, total protein present is actually being reported, flour has seven different proteins but only two are gluten forming (glutenin and gliadin) it is the property of these two proteins in forming "gluten" that is being reported by either wet or dry gluten weight/%. In some cases we can have a moderately high total protein content but still have a low wet/dry gluten weight/% due to the poor quality of the glutenin and gliadin either genetically or through chemical manipulation as in the case with a chlorinated high ratio cake flour.

[Re: Results of my Diastatic Malt Powder Enzyme Tests](#)**2890**

They put a whole new meaning to "folding the pizza" :-D

[Re: Round pie, square slice. What is up with that?](#)**2891**

John;

The produce bags CAN work BUT they are made very thin (probably 0.5-mil. in thickness whereas the Food Bags and bread bags are about 3 to 4-times that thickness. The thinner bags have a propensity of rupturing so if you are planning to use them be sure to double bag the dough balls. The bags that I use are 1.5-mil. in thickness and they work great, (1.5-mil. is the thickness of the average bread bag).

[Re: Neapolitan dough at 9000'](#)**2892**

John;

You can buy Food Bags from just about any supermarket in a roll for less than \$3.00 or you can buy a box of bread bags on the internet for about \$10.00 (just Google "plastic bread bags"). Your dough formula numbers look fine. Adjust the water temperature to 75F and be sure to record the finished/mixed dough temperature.

[Re: Neapolitan dough at 9000'](#)**2893**

TD;

Have you tried using the broiler function of your oven for baking the pizza? Even if it has a self cleaning function you might be able to get the oven up to a temperature where you can achieve some of the wood fired oven (hot bake) characteristics. If you go back through the archives here you will find discussion on both of these approaches. Have you considered a charcoal grill? Some members here use them quite successfully. As for a gas fired pizza oven as opposed to an electric one it all depends upon how hot the gas fired oven will get. In many cases there isn't much of a difference in maximum temperature but in other cases the gas oven can be hotter by 100 to 150F so you'll need to do some comparisons to see if a gas pizza oven is in your future or not.

[Re: Home oven versus wood-fired oven](#)**2894**

Don't worry about what the dough is looking like during the three hour period, this is to allow time for biochemical gluten development to take place, you will see what I mean when you do it. No, DO NOT use snack, sandwich, quart, two quart, one gallon or larger size Zip Lock bags, they are not the same and will NOT work as well as the recommended Food Bags. Why you ask? Because the Zip Lock bags will not drape over the dough in the same manner leaving air pockets where the plastic is not contacting the dough leading to condensation and stickiness of the dough as well as sticking in the bag. Additionally, you DO NOT want to zip the bag to close, if

you do the gas pressure can/will either tear the bag at a seam or pop it open at the closure resulting in a dry, crusted dough. By twisting the open end of the Food Bag into a pony tail and tucking it under the dough ball you allow the bag the ability to burp itself and expand as necessary. The bags can be saved and reused any number of times....but they are so cheap that this really isn't necessary for home pizza making.

If you can get the reverse spiral dough arm just mix the dough until it appears smooth, immediately scale and ball, oil and bag and place in the fridge (did you notice....no kneading). The dough will be ready to use in about 24-hours but it might be even better after 48 hours. This is where you can experiment to see what you like.

By the way, the oil on the dough ball is to help get it out of the bag after the fermentation period, the bag is what keeps it from drying out.

Don't over think it, now just get crackin' and makin' some pizzas, you've got friends and family depending upon you! :chef:

Let us know how your pizzas turn out.

[Re: Neapolitan dough at 9000](#) **2895**

We used reel type ovens quite a bit at AIB, two of which were Middleby-Marshall and two were Reed Oven Company. This is the same oven used in Chicago as the work horse for making both thin and thick crust pan style pizzas. Typical baking temperatures are in the 450 to 500F range though some will go as high as 550F. The difference being that our ovens, as well as most of those used in Chicago have a composite deck material as opposed to the steel decking which is really quite thin. Get a few pieces of un-glazed floor tile and place them on the shelves to preheat, then bake on the tiles to see if that helps the bottom bake. When we made pizzas in these ovens at AIB we actually had to use screens under the pan pizzas to prevent the bottom of the pizzas from getting too dark.

What was your baking time? In Chicago it runs right around 30-minutes.

[Re: help with ferris wheel Pizza oven](#) **2896**

Make your first series of cuts top to bottom then rotate 45-degrees and cut to to bottom again, is that the one you are looking for?

[Re: Round pie, square slice. What is up with that?](#) **2897**

And then two, followed by three, and if you're a micro-manager by any stretch of the imagination you will probably have changed your mind by that time, if not continue your quest to build an empire.

How can you tell if you're material for a multi-store operation with the potential of building it into a regional chain?

If you're a micro-manager....you are not.

If after opening your first store your life is in shambles....you are not.

If within 18-months of opening your first store you have not yet taken a vacation (and left your cell phone at home).....you are not.

If you feel that for whatever reason you cannot leave the store (you're a closet micro-manager).....you are not.

And there there's the financial backing....we won't even go there for now.

It's a lot of hard work but if you have the necessary skills and aptitude you have a reasonable chance to succeed. A very good friend of mine has three stores and he could go for more but right now finding good managers has been an ongoing problem.

[Re: Research. Interested in developing a Pizza Chain.](#) **2898**

John;

See if you can wrangle up a reverse spiral dough arm for your mixer too, you will be forever glad you did as the dough just keeps climbing up on that silly "J" hook. Even starting the dough using a flat beater aka paddle doesn't really help. You might be better off using biochemical gluten development to your advantage for now. To do this you can use your mixer with a flat beater to blend the dough ingredients together into something of a homogeneous mass and then transferring it to a suitably sized container. Oil the container, scrape the dough from the mixing bowl onto a floured surface, roughly form the dough into a ball and place it into the container, loosely lid the container and allow the dough to ferment for several hours, turn it out of the container and knead several times (you will see a huge improvement), then portion into desired weight pieces (250-grams) and form into balls, wipe with salad oil and place into individual plastic Food Bags (like bread bags), twist the open into a pony tail and tuck it under the dough ball as you place it into the fridge to cold ferment for 24+ hours. When you're ready to use the dough, remove from the fridge, allow to temper AT room temperature until the dough balls reach 65F (internal temperature) then open into skins by your preferred manner, dress and bake.

This is a pretty fool proof and low cost method to get started with, as you get more confident and hone your pizza making skills you can begin experimenting with different dough management methods.

[Re: Neapolitan dough at 9000' 2899](#)

So, what's your point? I used to think that all pizzas were delivered in a paper bag....until we moved away from the Chicago area in the mid 70's. :-D

The only down side to the party cut is that there are only four pieces which have any resemblance to being crispy, like you said, the rest is pretty soft but still GOOD! ;D

[Re: Round pie, square slice. What is up with that? 2900](#)

How are you planning to mix the dough?

The highest elevation that I've made pizza at is 9350-feet above sea level, is that close enough?

Due to the lower atmospheric pressure you can reduce the yeast level to 0.1 to 0.15% IDY. I would also increase the dough absorption to 65% or higher (absorption is dependent upon the flour used) but in your case you want to maximize it. Salt should be in the 2.25 to 2.5% range. Other than that, no changes to the ingredients. Any typical bread type flour will work well for you. My "go to" flour for home use is Pillsbury Bread Flour (targeted specifically for use in bread makers), the protein content is about the same as Full Strength (12.6%).

[Re: Neapolitan dough at 9000' 2901](#)

Paul Pizza;

Welcome!

You are absolutely correct about the dough being therapeutic, it keeps the mind active through creativity and problem solving plus it instills a lot of patience while providing us with a tasty reward in the end. Best of all, it things don't go exactly as planned, it's still pretty good tasting! :chef:

[Re: PIZZA AND DOUGH LOVER 2902](#)

Yael;

Great responses! :)

The only thing I might add is with regard to #4, what you call a "plate" we call a

"peel". A wood peel is referred to as a prep peel (it is the peel that the skin (dough) is dressed (topped) on and then peeled into the oven with. A small amount of flour, or more typically a blend of flour, fine corn meal and maybe semolina flour, (other materials are also used such as wheat bran and rice flour) is put onto the peel to facilitate peeling the dressed skin into the oven, this is referred to as "peel dust". A solid blade metal peel is referred to as an "oven peel" as it is the peel used to remove the pizzas from the oven with. While on the topic of peels, there is also a small round head peel which is used to spin the pizzas in the oven during baking, these peels are known as "spinning peels".

[Re: 8 questions](#) **2903**

That is correct BUT do keep in mind that you are getting a MUCH accelerated rate of fermentation at RT and you do under CF conditions so in a sense, yes your procedure is giving you a different crust flavor than "the same time of CF" but when presented to a trained sensory panel our experience is that they are unable to distinguish a combination CF and RT crust as compared to 100% CF or 100% RT. The method that we used at the time to ascertain that the amount of TOTAL fermentation was as close as possible to the same for all doughs was measurement pH and total titratable acidity.

[Re: Poolish diminishing returns ?](#) **2904**

The only time you're going to see any real flavor change between CF and RT is if you use 100% of either one.

[Re: Poolish diminishing returns ?](#) **2905**

A poolish is really nothing more than just a "liquid ferment" aka "brew" in baker's terms. The flavor imparted is not much different than that achieved through any other room temperature fermentation process so if you are using a poolish and fermenting the dough for 4 to 5-days the poolish will just contribute to the total fermentation equation adding to the fermentation flavor, aroma and all the other good stuff that comes with longer fermentation times but it will NOT distinguish itself by contributing a different flavor so there is really nothing to be lost, it's just part of the fermentation profile.

[Re: Poolish diminishing returns ?](#) **2906**

Well, it's hard to pin anything down there so I'll just add that insufficient salt can/will have a major impact upon the flavor of the finished crust and failure to allow the dough to warm to 50 to 60F prior to opening will reduce the amount of oven spring your dough can achieve which results in a more densa, compact crumb structure. Baking your pizzas at too low of a temperature can also have the same effect. While there are slight differences in flavor resulting from differences in flour the Allison bread flour (12.5% protein content if I remember correctly) and a regular flour (whatever that might be) will be negligible at best. Since your pan breads are typically made using very short fermentation processes and you liken the flavor of your crusts to those breads I'm thinking that your "recipe" might be out of balance and thus impacting total dough fermentation. You say that you are hydrating/activating the ADY in "warm" water, have you measured the temperature of the water to make sure it's within the recommended 100 to 105F temperature range? I have seen where the ADY was being hydrated/activated in "warm" water that was 122F (warm is a relative expression) which was adversely affecting the ability of the yeast to ferment the dough.

[Re: newb dough question + UK ingredients help!!](#) **2907**

Both PMQ and Pizza Today use what are called "stock" or "file" photographs, that's why they always look so pretty and set-up. We used them at AIB too, admittedly not always the best choice.

Remember the old adage about judging a book.

[Re: How does this happen?2908](#)

Also, if you can share your dough formula (in weight measures) as well as your dough management procedure it will help us to further assist you.

[Re: newb dough question + UK ingredients help!!2909](#)

Judith;

Let's begin by looking at your dough formulation:

Flour (semolina)	62.5%
Flour (high gluten)	37.5%
Dark beer (50-oz.)	19.53%
Ice (50-oz.)	19.53
Water (75-oz.)	29.29%
Dry yeast (type?) (weight?)	????
Salt (weight?)	????
Sugar (weight?)	????
Oil (20-oz.)	7.81%

I need to ask you to fill in the blank spaces before I can complete the formulation.

[Re: NEED HELP WITH MY PIZZA DOUGH2910](#)

Nancy's, Gino's, and Uno are the old timers in the Loop area. (Actually north of the Michigan Avenue bridge). Be sure to hit the Billy Goat Inn on Michigan Avenue immediately north of the bridge (west side), SNL made it famous...."cheeseburger, cheeseburger, cheeseburger".

[Re: Which are must try pizza places in Chicago?2911](#)

The visual change in dough density is not a very reliable means of assessing the fermentation rate. I think the key factor to zero in on will be the finished dough temperature and running the doughs side by side will help to rule out any environmental factors which might influence the dough.

[Re: Effect of sugar on crust flavor2912](#)

vtsteve;

30-seconds? That's forever and a day :-D

[Re: Need Some Help Making Larger batches of dough by Hand 2913](#)

Peter;

It doesn't bother me at all in that here we do things so differently. As I've said so many time before, when making pizzas for friends and family at home we can stretch the rules and take corrective action as we see it needed but in a commercial (pizzeria) setting FAILURE IS NOT AN OPTION, so we always recommend playing the conservative card, plus just ask any pizzeria operator if they feel comfortable letting the person who is mixing the dough make changes to the dough based on their own personal opinion.....betting there won't be many. But with the participants here we are much better versed in making pizza dough, recognizing problems/potential problems, and taking immediate corrective action which allows us to "bend" the rules, there is an inescapable price to pay for this though as you have heard me say many times, and that is that the pizza will be

different...good or bad, different is BAD at a pizzeria but it can be good for us in that it might be one of those ah-ha moments allowing us to make a better pizza the next time and those who are being treated to a pizza dinner will rarely complain if it isn't just like the last time they had your pizza. In my world I wear two hats, one is for the pizzeria where consistency and KISS is the name of the game and the other is worn when I'm making pizzas for family and friends in which case eating my pizza is like a trip to Walmart (if you find something you like at Walmart you had better buy it as they probably won't have it the next time you go there) the same is true for my pizza and cooking/baking in general, I'm always working to improve so it's never the same two times in a row (the one exception is my line of cakes: Double chocolate, coconut, nut cake; Lemon coconut cake and my orange cake, there were mentioned in an earlier post about desserts) In my opinion they're at my pinnacle of quality. But everything else is in a constant state of flux as I keep trying new/different things.....in my opinion, this is what keeps pizza going, my philosophy regarding pizza is "Dare to be Different" with the caveat if you are a pizzeria you must also be consistent.

[Re: Need Some Help Making Larger batches of dough by Hand](#) **2914**

Judith;

About all I can help you with at this time is to say that your flour to semolina ratio is way off. The total flour should not consist of more than 25% semolina flour unless you want to have finished crusts that would make a great substitute for shoe leather after delivery or carry out, or even just a slow eating experience in a dine in store.

In order to help you we have to get your dough changed from a "recipe" into a "formula" based on actual weight measures as opposed to volumetric portions as you have it now. As presented, I can't even determine what the dough absorption is as I have no indication of how much liquid is being added to the dough (a pitcher is a volumetric portion not a weight, and there can be many different speculations as to how big a "pitcher" actually is).

What you need to do is to have a scale capable of weighing your ingredients, then portion out each ingredient as you normally do but BEFORE you put it into the bowl weigh it and record the weight, this must be done for each and every ingredient, make the dough to ensure everything looks normal, or as it always looks. Repeat this three times, when done find the sum weight of each ingredient and divide the sum by three, this will give you the average weight of each ingredient in your dough "formula" from which we can accurately determine what corrective measures will need to be taken to achieve a crispier finished crust.

NOTE:

The dough formulation is only half of the equation we will also need to be able to see your dough management procedure as this can also have a great impact upon the final crispiness of the crust.

What are you baking your pizzas on (baking platform)? Pan, disk, screen? What is the color of the baking platform?

[Re: NEED HELP WITH MY PIZZA DOUGH](#) **2915**

Peter;

While I cannot say too much about PJ's, I can confirm your suspicion that they do not use a special dough for their dessert pizza.

[Re: What types of crust for dessert pizza?](#) **2916**

Peter;

I checked the referenced post and the 45 to 95F water temperature for suspending

CY (compressed yeast) is indeed correct. Since CY is already hydrated it is not sensitive to cold water temperatures like the dry yeast forms are. It's the hydrating of the dry yeast in cold water that has the deleterious effect of pulling glutathione out of the yeast, thus impairing its ability to ferment in the normal manner. In the commercial baking industry we use a form of yeast not discussed in these pages very frequently, this is cream yeast (yes, it is also known as CY) but it is a more common practice to refer to it as "cream yeast" so I don't have any concerns over referring to compressed yeast as CY BUT if the reference is in regard to a LARGE wholesale manufacturer I always make sure to confirm the type of yeast being referenced. Cream yeast is available only by the refrigerated tank car (like milk) and it is highly perishable so it is kept at a temperature between 38 and 42F throughout distribution as well as in the holding tanks at the bakery. At the bakery it is pumped directly from the holding tank to the mixer for immediate incorporation into the dough. The main reason for using cream yeast is \$\$\$\$\$ it's cheaper than any other form of yeast as it does not go through as much processing (to remove water) and there is no packaging involved except to pump it through a heat exchanger and into a refrigerated tanker for immediate delivery to the user. Compressed yeast (CY) contains roughly 70% water while cream yeast contains roughly 80% water which allows it to be fluid. By the way, cream yeast has a shelf life of 3-days at the bakery (when held beyond this time the yeast level in the products being made must be increased to maintain dough performance and product quality which can erode or wipe out any cost savings resulting from the use of cream yeast.)

[Re: Need Some Help Making Larger batches of dough by Hand 2917](#)

As one who is a FIRM BELIEVER in the KISS principle I try not to make things any more difficult or confusing than necessary so I always use my regular white pizza crust dough formula, after opening the ball into a skin I brush it with melted butter and then sprinkle it with a cinnamon-sugar mixture and begin building my dessert pizza from there. Aside from being simple and easy to make I've also found that by using this method the pizzas bake very similar to my regular pizzas....assuming I'm not baking at HIGH temperatures.

When making dessert pizzas in a hot oven (over 600F) I have found that baking the pizza on a screen for most of the baking cycle helps to control crust color while allowing the pizza to be sufficiently baked.

[Re: What types of crust for dessert pizza? 2918](#)

That's the amount of malt needed to bring an unmalted flour up to the same malt level as a regular malted flour.

[Re: Effect of sugar on crust flavor 2919](#)

Zaroh;

If you buy a spiral mixer you'll probably never need to buy another mixer again.

[Re: Proper term for this kind of dough mixer? 2920](#)

Two things jump out at me, your dough absorption at 60% might be a bit too low for what you are trying to accomplish, I suggest increasing it to 65% and the salt level is at 4% (about twice of what it should be) which is probably inhibiting the dough fermentation. Bring the salt level down to 2% (9.6-grams) and try it again to see if it's any better. Your IDY level is also outrageously high at 4%, I suggest bring it down to 0.5% (2.4-grams).

Make sure the water temperature is adjusted to give you a finished/mixed dough temperature of about 80F.

[Re: Advice](#) **2921**

A "normal" dosage for a 20L malt powder is 0.25%.

[Re: Effect of sugar on crust flavor](#) **2922**

Steve;

You might be right! I do remember that it was a "hill", and at my age that's an accomplishment by itself! :-D

[Re: Need Some Help Making Larger batches of dough by Hand](#) **2923**

Once you've seen the color change there is no missing it, I usually just mix until I see the color change and give it another minute, or so, before checking the dough to make sure it's sufficiently extensible to ball without tearing. As for mixing speed, I like to use the highest speed possible WITHOUT undue strain on the mixer.

[Re: Dough Texture to shoot for](#) **2924**

Unless you were adding enough sugar to slow the fermentation rate (highly doubtful) a small amount of sugar (2% or less) added to the dough formula would potentially speed up the rate of fermentation resulting in more of the classical "fermentation" flavor in the finished crust. Your comparison would be valid only if the finished (mixed) dough temperature for both doughs was the same as this will have a significant impact upon the rate of dough fermentation. Graig's idea of making the two doughs side by side and documenting everything is a good one, if you do it please let us know what you find out.

[Re: Effect of sugar on crust flavor](#) **2925**

Have you looked at the Eurodib mixers? I was looking at them while at Pizza Expo and I was impressed. You can get them in 20-quart size configuration/ 110v for well under \$1,000.00

[Re: Berkel Mixer](#) **2926**

We used to have a pair of small bench top Artoflex mixers when I was at AIB. They were about 20-quart capacity but lotsa luck finding one of those!

If you're interested in a dough mixer take a look at one of the 20-quart spiral mixers, they work great, very dependable, and pretty cheap too. We have had lots of discussion on spiral mixers here.

[Re: Proper term for this kind of dough mixer?](#) **2927**

C.G.;

When you say "yeasty" do you mean that the crust has a flavor like yeast or do you mean that it has a fermentation flavor/aroma? A good example of where we find a "yeasty"/yeast flavor is in Mom's home made bread and in some dinner rolls at restaurants where they are making them using a frozen dough.

[Re: Effect of sugar on crust flavor](#) **2928**

In the U.S. they're called Artoflex Mixers. They're designed to replicate hand kneading action. The most common application for these mixers is in making sweet and Danish doughs where you are looking for ingredient incorporation without excessive gluten development.

[Re: Proper term for this kind of dough mixer?](#) **2929**

You certainly can, and it's my error, Oops!

The number should be 169.3, it is the sum of all of the ingredient percentages.

The new ingredient amounts based on this correction are as follows:

Flour: 100% (2,600-grams divided by 1.693 = 1,535.73-grams of flour needed) Due to bowl loss we will round this off to 1,600-grams. The remaining ingredients will remain unchanged as the 1,600-grams of flour will still provide sufficient dough to make our 10 dough balls at 260-grams each with a small amount of dough to account for any bowl loss. In short, we're still "good to go" with the original dough formula.

I apologize for the error and confusion.

[Re: Recipe Help2930](#)

Everybody has their own favorite method of dough management, here's mine:

Add water to the bowl first, then add salt and sugar (if used), add flour, add IDY, Mix at low speed just until you don't see any dry flour in the bowl, add the oil and mix at low speed for 1-more minute.

Mix at medium speed for 8 to 10-minutes, or just until the dough appears smooth and has a satiny appearance.

Take the dough directly to the bench for scaling and balling.

Lightly oil the dough balls and place into individual plastic Food Storage Bags (NOT ZIP LOCK)

Twist the open end of the bag into a pony tail to close, tuck the pony tail under the dough ball as you place it into the fridge.

Allow dough to CF for 48-hours.

To use the dough, remove from fridge, allow to temper AT room temperature until the internal dough ball temperature reaches 60F.

Roll the top of the bag down to the dough ball, invert the bag allowing the dough ball to fall from the bag onto a floured surface.

Retain the plastic bags as they can be reused.

Open the dough balls into skins by your preferred method.

Place opened skin onto a dusted wood prep peel and dress to the order. (I like to use equal parts of flour, semolina and fine corn meal for my peel dust), everyone has their favorite concoction.

Peel the dressed skin into the oven.

Peel the baked pizza out of the oven using a metal blade peel.

Place hot pizza onto a screen or cooling rack for a minute prior to cutting and placing onto a serving tray. This allows the pizza to "steam-off" a little thus reducing the chances of the pizza getting soggy on the serving tray. There are any number of really good commercial items available to put between the pizza and the serving tray to further guard against the pizza getting soggy (just look to see what is being locally used in the pizza box for delivery pizzas). If nothing else, a corrugated pizza circle works well. For home use buy the size for the largest pizza you plan to make and let one size fit all.

Note:

If you want to get some great olive oil flavor in your pizzas pour some EVOO on the pizzas IMMEDIATELY upon removal from the oven, the heat of the pizza will "pop" the flavor.

[Re: Recipe Help2931](#)

Walter;

I haven't seen that done in eons! When we used to make bread I would pick-up the hot loaves not 5-seconds out of the pan to place them onto a rack for cooling. There is a little trick to it, it has to do with the way you place your fingers on the crust...not all at once.

[Re: Old school2932](#)

The dough looks pretty decent, the photo of the opened skin shows that you have too much dough out close to the edge so you're getting a thin center section. Continued practice will address that issue over time. It's something we all have to suffer through as part of the learning curve.

QD had asked about the "window pane" test where the dough is stretched using your hands to determine how clear of a gluten film can be formed by the stretching of the dough. While this can be used to determine when a pizza dough is properly mixed it is really hard for the novice to learn as there is nothing to compare it against. In bread production this is a very viable test for determining when the dough is properly mixed as we are looking for what is referred to as a "clear" film, none of the common spider webbing from undeveloped gluten that we see almost universally in pizza doughs (because pizza doughs are under mixed by choice). All of the work that we've done over the years points to minimum gluten development as being best for making pizza BUT we still need to mix the dough sufficiently so it isn't too sticky to handle reasonably well (especially during scaling and balling) without the need for excessive use of dusting flour or oil on the bench to facilitate dough handling. Once the dough takes on the mentioned smooth appearance the dough is almost always within 3-minutes of completion. Lower absorption doughs may be ready to go as soon as they've been mixed to a smooth appearance while a higher absorption dough might need those extra three minutes. It's impossible to be more specific than this as all doughs are different in so many ways, only experience will tell you for sure just how much mixing is actually needed. The one rule in mixing that I do follow essentially all the time is: If the dough is too sticky/tacky at the bench during scaling and balling in all probability it hasn't been mixed enough.

NOTE: If you are using a reducing agent in the dough (PZ-44 or "dead yeast"/RS-190) you will want to mix the dough JJJUUSSTT until it BEGINS to take on a smooth appearance...NO MORE! It will have a slightly sticky/tacky feel to it at the bench but that's normal for a dough with a reducing agent in it. The reason why mixing is so critical when a reducing agent is used is because the reducing agent continues to work all the way to the oven, it's going to continually get softer even if it's just sitting there in the cooler as a dough ball.

[Re: How to Mix Pizza Dough so it's ready to use?2933](#)

Steve;

Assuming a total dough formula percentage of about 167% you will need to have 10 X 260-grams = 2,600-grams of total dough weight. If you divide 167 by 100 = 1.67. Now just divide 2,600-grams by 1.67 = 1556.88-grams of flour. To allow for bowl loss round that up to 1,600-grams of flour. So, your dough will need to be based on 1,600-grams of flour to have sufficient dough to make 10 dough balls at 260-grams each. Sorry about the math, I'm "old school".

Here is a potential starting dough formula:

Flour: 100% (12.2 to 13.8% protein content aka strong bread flour) (1,600-grams)

Salt: 2% (32-grams)

IDY: 0.3% (variable depending upon your dough management procedure) (4.8-grams)

Oil: 1% (16-grams)

Water: 66% (variable) (1,056-grams)

Total % = 167%

I'm not sure I'd really want to get that oven dirty! :-D

[Re: Recipe Help2934](#)

When it comes to mixing pizza doughs I've not seen a better mixer type than a spiral.

[Re: Best Spiral Home Mixer2935](#)

Actually, I was going to say "trees" :-D

[Re: good source of wood in Arizona2936](#)

Hey Steve;

Welcome!

Just over the past few days we had some discussion on hand mixing dough as well as use of different yeast types in hand mixing situations.

What dough weight are you planning to use for each skin? This will give us an idea of the dough weight needed for 10 skins allowing us to size a dough formula appropriately for you.

Do you have a scale capable of weighing in grams?

[Re: Recipe Help2937](#)

Sucrose is inverted into the sugars dextrose and fructose which are nutrients for the yeast during the dough mixing process by the enzyme "invertase" which is present in the yeast. It is only the residual sugars that participate in crust color and flavor (sweetness) development. Sucrose by itself will not caramelize (this is why angel food cakes remain so white in color). Try making an angel food cake using dextrose (a reducing sugar) to replace the sucrose and you will end up with a very muddy brown colored cake, not just on the outside but on the inside too.

[Re: Effect of sugar on crust flavor2938](#)

And unlike taxidermy as a hobby, you can eat your mistakes! :-D

[Re: do overs2939](#)

Sucrose will not be detected flavor wise in the finished crust until you get into the 4% and above range. Try a Papa Murphy's pizza if you want to see what 5% sucrose tastes like in the crust...sweet. Remember, with malt you have two decisions to make, diastatic or non-diastatic. Diastatic malt is enzyme (amylase) active and it PRODUCES sugar in the dough by converting damaged starch already present in the flour into dextrins and/or maltose (sugars which are fermentable by bakers yeast) and also participate in the browning reaction to provide crust color. You typically don't get a sweet flavor from malt like you do from high levels of sucrose but you will get a malty (think malted milk balls) flavor instead and you can also get the baggage of unwanted dough softening, the amount you get will be determined by the degree L of the malt you're using as well as the total amount of damaged starch present.

Non-diastatic malt is used just for its flavor impact as well as a little sweetness it can provide to the crust with residual malt participating in crust color development. In many cases non-diastatic malt powder is used for its darker (more reddish) the correct term is "foxy red" crust color contribution, this is why it is so widely used in bagel production. Because you don't have the limitations, due to enzymatic activity, with the non-diastatic malt you can use as much as you want/need to achieve your end goals for using it. At lower levels it provides what is described as a "nutty" flavor but as the level of malt increases this turns into the classic malty flavor.

There has been much discussion on malt and how to use it if you're not familiar with using it.

[Re: Effect of sugar on crust flavor 2940](#)

I agree with Craig, when looking at the pictures those were my first thoughts too. The whitening effect of oxidation is only seen in the interior (crumb portion) of the crust, not on the exterior (crust) portion. When we did our research many years ago comparing bleached v/s non-bleached flours in white pan bread production we always saw a brighter, whiter crumb with the bleached flours but never saw any difference in the crust color between the two. This was important for us to know at the time as the industry was moving towards the use of un-bleached flour and we wanted to know what other affects might be encountered (aside from a creamy/yellowish colored crumb) in all types of bread production.

[Re: Does autolyse gives a whiter final crust ? 2941](#)

Tin plated steel pans as well as "bright" aluminum pans that have been seasoned should NEVER be washed in a typical manner, and NEVER, EVER soak them in soapy water as this will ensure that the seasoning (which is really nothing more than a polymerized (think varnish) finish will begin to peel off like a bad sunburn. To clean these pans just dip in warm soapy water, immediately gently scrub with a SOFT bristle brush, then IMMEDIATELY rinse in clear water, towel dry and then oven dry. Do this and you won't have any problems with the seasoning peeling off, don't do it, and you're likely to be trying to figure out how to strip all of that beautiful seasoning off of your pans and starting the seasoning process all over again. By the way, I skipped the sanitizing step that comes into play after the rinse as you are a home pizza maker, but if you have a pizzeria you are well advised to include the sanitizing step just to stay on the happy side of your local health/sanitation inspector.

[Re: Washing Pizza Pans 2942](#)

If anybody is from the Pittsburgh, PA area there used to be a pizzeria in the (I believe it was referred to as the School Hill area) where the owner makes all of his dough by hand, quite a sight to watch him.

[Re: Need Some Help Making Larger batches of dough by Hand 2943](#)

JPB;

Not following your question?

[Re: Bulk cold ferment or ball then cold ferment? 2944](#)

You've got the right picture. We make croissants in a very similar manner. Another, though more labor intensive method is to scale the dough and ball it immediately after mixing, cold proof it and then open it by making multiple passes through a standard pizza sheeter/roller, the skins will be near finished size though just a little larger. The skins are placed on a screen and trimmed to final size. This method typically generates 10 to 15% scrap dough while the method using a reversible sheeter will typically generate upwards of 45% scrap. This is an important consideration since the amount of scrap added back to new dough MUST be controlled if you are going to have a consistent quality finished crust. When working with a sheet and die cut line here is a typical scenario; The amount of scrap return is not controlled (whatever scrap is generated is added back to new dough) the variable amount of scrap dough creates variability in the way the dough stretches and contracts (extensibility and elasticity) resulting in the generation of additional scrap which is again, all added to the new dough, resulting

in even more variability which results in even more dough processing issues, etc., etc. You can see what happens when the amount of scrap dough isn't controlled....nothing good ever comes of it. The level of scrap dough where it has little impact upon the dough is 15%, any more than that just means more work for you. But the line is generating 45% scrap dough, what do I do with the other 30% scrap? (question most often asked). The answer is simple, find another use for it. Bread sticks are commonly made from this scrap dough as they are easy to make and have a broad spectrum restaurant application, you could also use it to make rustic type breads and rolls where in this case the scrap dough can be used much like a sponge (sponge and dough process) at levels of up to about 80%. Just some food for thought.

[**Re: How To Increase My Crust Production**](#)**2945**

Kreskin;

Have you given any thought to using a reversible sheeter with a cutting/forming table (this is where take-away conveyor is about 6' long allowing for a die cutting roll to be installed or you can manually pass a die cutting roll over the dough sheet. If you really want to automate I would use the reversible sheeter to sheet the dough to the desired thickness, roll it on a baton and take it to a cutting table where the dough is unrolled from the baton and individual pizza skins are cut from the dough using a hand held die cutter. While this is taking place the next dough is being sheeted and rolled making the process quite fast.

Note: The die cutter in this case is not the biscuit cutter type as you might be presently using but instead it is a rotary die cutter looking more like a giant rolling pin so it continually cuts skins from the dough sheet as you roll it along the length of the ribbon of dough.

Just something to think about.

[**Re: How To Increase My Crust Production**](#)**2946**

Here's something to remember, the "flash point" of most food grade oils is about 435F, meaning this is the temperature at which the oil can ignite. This is the reason why it is highly recommended that any future seasoning you do be initially done at not more than 425F, then after the oil has polymerized (formed an amber colored finish) you can crank up the temperature to further darken it without fear of all the excitement that accompanies an oven fire.

[**Re: Smoke in oven**](#)**2947**

Cracker doughs and dough presses do not play well together, sheeting them is the only real way to get a decent crust with the same characteristics that you are getting from your present procedure which involves sheeting the dough.

How to speed up your operation? First thing we need to know is what your present procedure is, from there we might be able to suggest changes, or if you wish, please feel free to call me at 785-537-1037 and I will be glad to review what you are presently doing and suggest some possible changes that might help speed things up a bit. As I am not always at my desk, please send me an e-mail at <thedoughdoctor@hotmail.com> letting me know when you plan on calling.

[**Re: How To Increase My Crust Production**](#)**2948**

I put the flour in the bowl and create a crater in the middle of the flour all the way to the bottom of the bowl then pour in the flour and begin mixing by pulling in the flour a little at a time as I stir it. I like to use a plastic bowl scraper to clean the flour and dough off of the sides of the bowl after I've got all of the flour incorporated. Mine you, this is a hand held, flexible bowl scraper not one of those

Rubber Maid bowl scrapers which are designed for use with batters only.
[Re: Need Some Help Making Larger batches of dough by Hand 2949](#)

I do essentially the same thing that Steve does when making unusually large batches by hand with one exception, I always like to mix the salt, sugar (if used) and yeast into the water immediately prior to adding the water. This ensures thorough dispersion throughout the dough. Remember, if you are using IDY, like ADY it must be suspended in a small portion of 95F water prior to addition to the dough water. If you're using CY you can just crumble it right into the dough water and whisk to suspend it and you're good to go. As for the fat, I prefer using oil as opposed to shortening for ease of incorporation but if you must use a plastic fat it's better to melt it and add it slowly during the mixing process. When adding the oil I will add it to the dough towards the end of the mixing process and let the following kneading process work it throughout the dough mass.

[Re: Need Some Help Making Larger batches of dough by Hand 2950](#)

From a fermentation standpoint, no but from a dough handling standpoint the answer is probably yes. When you bulk ferment you will still need to subdivide the dough by scaling and balling and then wait sufficiently long for the dough balls to sufficiently relax so they can be easily opened into skins. In my opinion it is just a lot easier to put the dough into balls right up front and then open a well fermented dough ball (rather easily) into a skin. This also eliminates the question of how long to wait before opening the dough balls after "bulk" fermentation.

[Re: Bulk cold ferment or ball then cold ferment?2951](#)

Welcome to New York City! Goes to show you that even in NYC there are so many versions of pizza that it is impossible to keep track of. This didn't surprise me either when I did my tour as when it comes to pizza, if you don't like one pizza, try another until you find what you like.

That soft, limp slice is what caused me to develop my "new approach to pizza by the slice" which you can read about in PMQ Magazine if you search it out in the archives or go Google AJ's New York Pizzeria, Manhattan, Kansas where you can see it in application.

The extreme variety that we see in pizza is the driver that makes pizza so popular, and truth be known, I wouldn't want it to be any other way! :chef:

[Re: NY slice joint tour2952](#)

Bulk fermentation is characterized by a steady progression in fermentation. The outside ambient temperature will have little or no effect upon a true bulk fermenting dough. There are two reasons for this, one is because the dough, as it ferments becomes less dense so it is a better insulator thus preventing the core/center of the dough form being influenced by any outside temperature. The second is due to the heat of metabolism, as the yeast ferments it also creates heat (about 1F per hour), this results in a very steady and progressive rise in temperature which is really quite predictive which is an important aspect to managing dough.

[Re: Bulk cold ferment or ball then cold ferment?2953](#)

Yes, there just isn't sufficient dough mass to give you the typical characteristics of bulk fermentation.

[Re: Bulk cold ferment or ball then cold ferment?2954](#)

Amazing! :-D

I never knew anything like that existed aside from a dough descriptor.

You learn something new each day.

I wonder if the name is a befitting for that stuff as it is for the dough?

Thank you.

[Re: Elasticity, Extensibility & Tenacity, Oh My! 2955](#)

Rolls;

Your comment on the "over mixed" dough was interesting. It is very difficult, if not nearly impossible to really over mix a dough without some type of high speed machine mixing. With any type of low speed mixing, especially with kneading you are incorporating air/oxygen into the dough which oxidized the gluten bonding points on the gluten chain which re strengthen it. At one point some time ago I discussed the fatigue dough method of dough mixing which utilizes this to great advantage, with high speed mixing you can open/extend the gluten and allow the addition of more water (like an autolyze but without the need for time), the mixer bowl is then opened and the dough is allowed to continue mixing for several minutes at low speed. The opened bowl allows air to enter into the mixing chamber (horizontal bar type mixer) and the low speed mixing allows for a pulling/stretching, and folding action to take place which effectively incorporates air/oxygen into the dough which restrengthens the gluten giving the dough normal handling and processing properties. This was the preferred mixing method of the old Continental Baking Company (same folks who brought you Wonder Bread/"Builds strong bodies 12-ways" in reference to the twelve enrichment ingredients). Back to the point: From your description it sounds as if you had mixed the dough to a point of full or near full gluten development. Full gluten development is defined as mixing the dough to a point where the gluten is developed to provide maximum dough strength which we see as a very stiff, tight dough consistency in the mixing bowl. You only see this when you develop the gluten by some form of mechanical means, when you achieve full gluten development through biochemical means the effects of the formed acids and the enzymes also provide a softening of the dough at the same time so what you end up with is a dough with a fully developed gluten structure but without the elasticity associated with a dough mechanically mixed to full gluten development.

[Re: Elasticity, Extensibility & Tenacity, Oh My! 2956](#)

QwertyJuan;

Note in my original response (heavy tomato puree), the answer to your question is behind door #2. Your assumption is correct. ^^^

My all time personal favorite is nothing else but the Stanislaus 74/40 tomato filets with a little fresh garlic and a few fresh basil leaves placed on the skin just prior to application of the filets, great fresh, ripe tomato flavor with a superb texture. With the filets you don't need to go for 100% coverage like you do with a sauce, but instead go for about a 1" spacing between the tomato filets.

[Re: Sauce 2957](#)

Rolls;

An over mixed dough "lets down" during the mixing process, this means that the gluten structure becomes weakened to the point where the dough loses its elastic nature and begins to take on more of the characteristics of a batter, yes, pourable in extreme cases, in the baking industry the slang term for this is "elephant snot", not very pretty, but you get the picture. In this condition the dough is STICKY, has a very shiny appearance (due to loss of water holding properties of the gluten) and if you grab onto a piece of it the dough will stretch with no effort at all and continue

to stretch for a country mile. I believe the Pyler book, Baking Science and Technology, by E.J. Pyler has some pretty good pictures of this. We've referenced this book a number of times in the not too distant past.

One of the very first things that I looked at when I first began my life's research on pizza was to identify the technology controlling the making of pizza dough. At the time the general belief was that pizza doughs were for all practical purposes the same as a bread dough but it didn't take too long to dispel that belief. This perceived similarity in dough technology is perhaps why we see some terms used in bread making also applied to pizza dough. They're not necessarily wrong, but they just don't fit well and "dough tenacity" is one of those terms. Another mixing term that falls into the same category is "pick-up" To the bread maker this is the point in time during mixing the dough where the dough begins to come together as a mass, in pizza production this might be all the mixing the dough will receive so it might be referred to as fully mixed at this point but due to so very many differences in dough formulation this term does not work well in pizza dough production as a thin crispy type of dough with 40% absorption might exhibit this characteristic at a very different stage of gluten development than a Domino's type of dough with an average of 60% absorption. Full gluten development might also be said to be one of those terms too as there are few pizza doughs mixed to "full" gluten development, the exceptions which come to mind are doughs for frozen pizza dough and emergency doughs, essentially all other pizza doughs are under mixed to a greater or lesser degree. These are the things, among many, that I had to unravel back in the mid 60's.

[Re: Elasticity, Extensibility & Tenacity, Oh My!](#) **2958**

Oven brooms are made from metal so there is nothing to melt or burn. If you're cleaning the deck with anything that melts or burns you're using the wrong kind of brush. The metal bristles on an oven brush do a very good job of removing all but the baked on debris, for removing that stuff you will need an oven rake, fortunately most of the time the two are combined so there is nothing else to buy.

[Re: Brush for cleaning](#) **2959**

Q.J.

No, it is not, in fact, tomato paste is bitter, probably not the flavor you are looking for. To start, I'd suggest changing over to 7/11 (also a Stanislaus product). The 7/11 is made from whole "unpeeled" tomatoes so it provides a much richer tomato flavor and might be just what you are looking for, if you still want more flavor and want to "go for broke" begin blending some Saporito (also from Stanislaus) which is a heavy tomato puree, into the 7/11 until you get something that your customers like. If you go this route I'd start with 75% 7/11 and 25% Saporito and bench mark from there.

[Re: Sauce](#) **2960**

The dough looks OK to me, but the real question is, did it make a good pizza? That's the only real way to tell is a dough has been properly fermented for making whatever you are trying to make with it. If it did then all you need to do is to replicate the dough formulation, all temperatures and time will become a relative constant in your equation for success.

[Re: Dough after Bulk Rise](#) **2961**

Oh, that's easy! They're called "works of art"! As in now here is one of my works of art, enjoy! :chef:
We just don't tell them Art who, you all know him, he's the guy who steps in

occasionally and makes a pizza for use once in a while that turns out really great, better than anyone's expectations, and then rides off into the sunset like the Lone Ranger. :-D

[Re: Elasticity, Extensibility & Tenacity, Oh My! 2962](#)

Rolls;

If you want it in "Lehmann's Terms" you'll have to go to PMQ Magazine :-D, but to save the trouble I'll try my best here.

Elastic: Think of the properties of a piece of elastic, you deform it and it quickly returns to its original shape. I used to use the example of a rubber band, stretch it out to 12-inches long and let it go and it returns to its original length.

Extensible: This is the ability to be stretched (easily extended), when this adjective is used it carries with it the inference that when extended to a specific length or shape the dough will not retract or try to assume its original shape. A good synonym might be "stretchable".

Tenacious: Throughout all my years in the food industry, I think I might have heard this word used only a handful of time to describe the properties of a dough. When it was used it was always used to describe a dough that was tough, difficult to handle, generally, but not always, somewhat sticky. Where I've heard the term used most was to describe a dough that was difficult to discharge from a horizontal mixer, as in "The dough was tenacious and difficult to kick out of the mixer". I've never heard it used interchangeably with "elastic". While "bucky", as in a bucky dough, might seem similar to a tenacious dough it is not as a bucky dough is used to describe a dough that resists deformation, it just springs right back when you try to deform it in any way, and if you force it against its will it just rips or tears apart as in "The bucky dough was shredded by the reduction rolls as it went through the sheeter". Bucky doughs are almost always accompanied by a lot of gas bubbles in the dough as in an over fermented dough condition.

Did that un-muddy the waters, or just make it worse?

[Re: Elasticity, Extensibility & Tenacity, Oh My! 2963](#)

Walter;

Actually, they are a 4-speed mixer, an "H" shifting pattern too. :-D

[Re: What model of dough mixer is this!? 2964](#)

Rolls;

It is very much a dough mixer.

[Re: What model of dough mixer is this!? 2965](#)

Easy! Use Pi X R squared. This will give you the surface area of a circle.

For example, if you are making a 12-inch pizza and you use 10-ounces of dough for the dough ball:

Pi = 3.14 (approximately)

R = radius (1/2 of the diameter)

Squared = radius X radius

Radius of a 12-inch circle is 6-inches, $3.14 \times 36 = 113.04$ square inches.

10-ounces divided by 113 = 0.08849-ounces of dough per square inch of surface area.

Now you know the "dough loading" (weight of dough per square inch of surface area for your pizza). To find the dough weight for ANY other size of pizza just calculate the surface area for the new pizza and multiple it by the dough loading (0.08849)

20-inch pizza:

$3.14 \times 100 = 314$ -square inches.

$314 \times 0.08849 = 27.78$ -ounces (round it off to 27.75-ounces).

Ain't math great?

By the way, you can use this for estimating the amount of sauce and cheese too. :)

[Re: How to figure out the weight for Dough Balls of Different Sizes?2966](#)

Craig;

You're correct, (M-80 model has a closed base and the M-800 has an open base, otherwise the same) it is the best and I might add, the most powerful mixer EVER built by Hobart. It has an automotive clutch as well as an automotive transmission. The only problem those mixers ever had was due to their great power, they were known to break agitators, and main shafts and if the shaft didn't break the seal was always damaged as well as the bearings (this is evidenced by oil leaking at the shaft), this was all brought about by the power of these mixers and the low absorption pizza doughs of the time. I had one for many years, by the way, much like a P-51 Mustang, they have a very unique sound when you start one up...kinda sounds like a beast being fired up, which ain't entirely wrong!

[Re: What model of dough mixer is this?!2967](#)

With that amount of IDY probably 3-days on the outside, re-ballng "might" get you an additional day, I wouldn't hold my breath on it though.

[Re: Help! How long can I cold ferment? 2968](#)

Not a bad first run at it! As you've discovered, they all taste good and that's the best part of learning, you get to eat your mistakes too. Stay at it and soon you'll be inviting friends over for pizza dinner! :chef:

[Re: My first pizza!2969](#)

Here is a dough formula that should get you started;

Flour: 100% (bread type flour)

Salt: 2%

Sugar: 2%

Oil: 2% (add by delayed oil addition mixing method)

Yeast: 1% IDY

Water: 56%

Hard Fat Flakes: 12% (these are added TO the dough after it has been mixed to within 4-minutes of completion) If you cannot get the hard fat flakes you can make your own by freezing Crisco and then shaving and chopping it into flakes about the size of rolled oats. Keep frozen until ready to use and add to the dough directly from the freezer. After mixing take the dough to the bench and roll out to about 3/16-inch thickness, cut into 7-inch diameter circles, add precooked filling, brush 1/2 of the edge with water and fold over (dry over wet), crimp the edges well and par-bake at 425F until just lightly browned. Refrigerate or freeze for later use or bake until the internal temperature reaches or exceeds 165F.

If you want more crust color brush the dough with whole milk, oil, or egg wash depending upon how dark you want the crust to be. Steam vents are not typically used BUT YOU HAVE TO WATCH THE INTERNAL TEMPERATURE CAREFULLY! If you get the IT too hot they will blow every time.

[Re: Hot Pocket2970](#)

Can you provide the following information?

- 1) Tell us as much as you can about the flour you're using.
- 2) How much and what kind of yeast did you use when making the dough?
- 3) Percent salt used?
- 4) Percent sugar used? (if used at all).
- 5) What was the finished (mixed) dough temperature?
- 6) Did you allow for and fermentation prior to putting the dough in the fridge or did you go straight from the mixer to the bench for scaling and balling and then directly into the fridge?
- 7) Did you cross-stack or leave containers uncovered for at least two hours after placing in the fridge? No need to do this if using bags.

If you can fill in these blank spaces we might be able to be a bit more specific.

[Re: Help! How long can I cold ferment? 2971](#)

I don't think anyone is going to be able to help you from the dough standpoint, I know if I could I wouldn't be where I'm at right now, I'd be sitting out on my own private beach on some secluded Caribbean island sipping a cold drink with a little umbrella placed on top of it. What you are asking for is the Golden Fleece of the retail pizza industry. Your best bet is to consider using boxes with steam vents, one of the many mats used to hold the pizza up off of the bottom of the box allowing for ventilation of the bottom crust, reducing the amount of vegetable toppings (reduces moisture in the box) and being a little sparse on the sauce (sauce, like the veggies, is almost 90% water). Additionally, be sure to allow the pizzas to steam off for at least 30-seconds before boxing them as this practice will also reduce the moisture which is trapped in the box.

If you search back through archived posts you will find that we have discussed this not too terribly long ago and you might be able to glean a few more nuggets of wisdom from one or more of those posts.

[Re: Chewy base 2972](#)

I forgot to add that while you aren't burning gas so products of combustion are not an issue, you will still probably want to be venting the oven to get rid of the acids, alcohol and carbon dioxide coming off of your pizzas during baking. Failure to do so may leave everyone in your store rubbing their burning, irritated eyes in short order.

[Re: Infrared pizza oven 2973](#)

I'm not an engineer qualified to really answer your questions so I'll leave that to someone better qualified than I am. I can however say that infrared has been used in pizza ovens here in the U.S. for many years, I worked with some of the first commercial IR pizza ovens back in the mid 70's, Domino's even used them for a while. Heat/temperature recovery of the baking deck will be your greatest challenge as the emitter temperature will not be as hot as a gas flame or resistance heating in direct contact with the deck so you might want to think about going thicker with the baking deck material, I'm thinking that twice as thick as you have proposed would be better for holding heat as you will be baking on latent heat (as you have large production ovens for consideration I'm assuming you will be using this oven in a pizzeria application where you will need to bake multiple pizzas back to back without much time for heat recovery).

These are just my thoughts.

[Re: Infrared pizza oven 2974](#)

Your stone temperature is OK but don't use your infrared thermometer for

measuring the dough temperature when determining the time to open the dough balls as in this case we are referencing the internal dough temperature so a stem or dial type thermometer must be used unless you have an electronic thermometer with a cabled thermal-couple which can be inserted into the dough. Your infrared thermometer is only effective for measuring the surface temperature (which will be lower than the internal temperature in most cases).

[Re: How to Mix Pizza Dough so it's ready to use?2975](#)

I grew them year before last and I agree with what you say about the flavor. While I don't use a traditional sauce very often I mostly just slice the tomatoes, blot them dry and apply to a very lightly oiled skin just as they are and call it my "sauce". Really great flavor. I also had a bunch of black, cherry tomatoes which had a fantastic flavor. I dried these for use as you would sun dried tomatoes....FABULOUS!

[Re: Black/purple tomatoes2976](#)

You don't use the rolling pin on the crust, you only use it on the dough when opening the ball into a skin. By using a rolling pin to open the dough to about 2-inches LESS than full desired diameter you DO NOT degas the dough or significantly alter the cell structure in the dough as you would by opening it to full diameter using a rolling pin or pastry pin. Just be sure to use it correctly.

- 1) Pin the dough out from different directions by turning the dough often.
- 2) Use many light to moderate pressure strokes. Never try to open the dough using a couple of heavy pressure strokes.
- 3) Never allow the pin to roll off of the edge of the dough....that's a "golden rule".
- 4) When using a rolling pin always place your thumbs ON TOP of the handles, never on the bottom. This will provide much better control and application of more even pressure to the dough.

[Re: Pizza under carriage wet in the middle 2977](#)

Rolls;

You are ABSOLUTELY 100% spot-on! ^^^

[Re: Fermentation and Temperature2978](#)

Cherubino;

Regarding your question on dough ball temperature, please refer to my Response #5 above, Item #8.

As for the ingredients, not really assuming you have a decent flour to begin with (like a bread flour), the main factor responsible for that easy to open characteristic is fermentation and to a lesser extent dough absorption. The comments posted by Rolls is "spot-on".

With all of this said, there are certain types of ingredients that can give you the dough characteristics depicted in the video. These ingredients are referred to as "reducing agents" they break down the gluten chains making the gluten form faster during mixing while at the same time giving a much more extensible (though weaker) gluten film after mixing. The two most commonly used reducing agents are glutathione aka dead yeast and L-cysteine/L-cysteine hydrochloride which is the active ingredient in the ingredient PZ-44 (a blend of dairy whey and L-cysteine). To a lesser extent one can also achieve a more limited reducing effect by adding onion and/or garlic to the dough. Some milk proteins can also exhibit a reducing effect but it is very inconsistent (this is why if you read old cooking and baking books they will always call for scalding the milk prior to using it in making breads and pastries. The scalding denatures those proteins and eliminates the

reducing effects of the liquid milk. Bet you didn't know that! :chef:

[Re: How to Mix Pizza Dough so it's ready to use?2979](#)

This can also result when the skin is improperly opened resulting in a very thin center section so when the dough rises in the oven the edges rise higher than the center forcing the moisture and fat to flow to the center of the pizza and with a very thin center section the moisture and fat soak into the crust resulting in what you are seeing.

If you're having a problem opening the dough uniformly try this:

Use a rolling pin or pastry pin to open the dough to about 2-inches less than the desired diameter, then hand stretch the dough the last two inches or so. This will give you a much more uniform dough thickness across the entire diameter of the skin. With time and practice you will become better at opening the dough and you'll be able to put the rolling pin or pastry pin away.

[Re: Pizza under carriage wet in the middle 2980](#)

Mixing the dough JUST until it comes smooth in the bowl is pretty well a standard mixing procedure for all but two methods of handling or managing the dough. The two exceptions are when making an emergency/no-time dough where we will not be fermenting the dough for a sufficient time for biochemical gluten development to take place and when making a frozen dough where the dough will be frozen before any significant fermentation takes place. In both of these cases the dough needs to be mixed to full gluten development, this is a point in gluten development where the dough becomes soft and extensible during the mixing process.

By the way, bread doughs, unlike pizza doughs are mixed to full gluten development since they only receive limited fermentation.

If you want to see a pizza dough being mixed go to my web site at <www.doughdoctor.com> and you will be able to watch one of my PMQ videos showing the mixing of a pizza dough.

[Re: How to Mix Pizza Dough so it's ready to use?2981](#)

As you watch the dough develop during mixing it goes from shaggy to having a curdled or "brain like" appearance then as mixing progresses you will see what appears to be a color change as the dough becomes lighter in color (actually it is not a color change at all but instead it is due to the dough becoming smoother and reflecting more light), once it reaches this point you are close to being finished with the dough mixing (the dough is normally sufficiently mixed about 2-minutes after you see this change in the dough. Additional mixing is not needed nor desired and it just puts more wear and tear on your mixer. Biochemical gluten development will take care of the rest of the gluten development for you during the fermentation period.

[Re: How to Mix Pizza Dough so it's ready to use?2982](#)

Mjs16;

Neeever Mind. You've got that base already covered. ;D

[Re: Making Neapolitan Pizza Dough - Rising and forming pizza 2983](#)

Here is a very simple and basic procedure for you to follow to make your pizza dough.

1) Use 60F water temperature when making your dough. We like to see a finished (mixed) dough temperature between 70 and 80F).

2) DO NOT add the oil right away, instead, mix the dough JUST until all of the flour is picked up in the mixing bowl, THEN add the oil and resume mixing. Be sure to

measure the temperature of the mixed dough as this is very important.
3) Mix the dough JUST until it has a smooth appearance...no more than that.
4) Remove the dough from the mixing bowl and immediately take it to the counter for scaling and balling.
5) Lightly oil each dough ball and place it into a bread bag....NOT a Zip-Lock bag.
6) Twist the open end of the bag to form a pony tail and tuck it under the dough ball as you place it in the fridge.
7) If you can make 3 dough balls that'll be great. Remove one dough ball after 24-hours and one dough ball after 48-hours and the last one after 72-hours in the fridge.
8) When you remove the dough ball allow it to temper AT room temperature until a thermometer, inserted into the dough ball, shows 60F, then begin opening the ball into a skin for dressing and baking.
9) Repeat #8 with each dough ball.

This will allow you to see how your dough handles at 24, 48 and 72-hours allowing you to see how the progression of time in the fridge impacts both the dough and the finished crust characteristics which will let you decide which one you like the most. Take a lot of pictures and notes along the way.

Good picture shots:

Immediately after mixing.

Dough immediately after balling.

Dough in bag immediately upon removing it from the fridge.

Dough just before removing it from the bag.

Dough after being opened into a skin.

Dressed skin.

Baked pizza.

Smile on your face as you're eating your pizza. ;D

One other thing, how to remove the dough from the bread bag:

Roll or pull the bag down around the dough ball then invert the bag allowing the dough ball to fall free from the bag onto a floured surface, dust both sides of the dough ball and proceed to open it into a pizza skin.

After using the bag method you can experiment with different types of containers if you wish.

[Re: How to Mix Pizza Dough so it's ready to use?2984](#)

From the sound of your question your dough doesn't look like that...how does it look? What is the finished (mixed) dough temperature? I seldom, if ever mix my doughs to that consistency unless I'm making a no-time/emergency dough. A typical pizza dough, regardless of the type of mixer used, is only mixed to a point where it has a smooth, satiny appearance. When doughs are mixed more than that you begin to lose some of the desirable open, porous crumb structure characteristics....the crumb structure of the finished crust looks more like that of bread than pizza.

[Re: How to Mix Pizza Dough so it's ready to use?2985](#)

I see you're using "00" flour, unless you're baking at 800F or more you would probably be better off using one of the other regular white flours such as King Arthur Bread Flour or Pillsbury Bread Flour (designed for bread making machines and available at just about any supermarket).

[Re: Making Neapolitan Pizza Dough - Rising and forming pizza 2986](#)

The last time we moved deck ovens we had six college students, a few beers and the promise of a free pizza dinner, and my pick up truck.

You might want to run your post over at the PMQ Think Tank too, we have a number of Canadians tuned in over there who might be able to add something to the discussion <www.pmw.com>

[Re: Serial number and model number](#) **2987**

Actually, Food Bags are better than Zip Lock bags, the reason being that it is possible for the gas pressure within the bag to either pop the seal open or actually split a seam open in the bag which will allow the dough to both seep out as well as dry out, additionally many people like to have the dough ball retain a round shape during the fermentation period as this can make the ball easier to open into a round skin....Zip Lock bags are really not conducive to this. Food Bags (they look just like bread bags) are cheaper to use and are better at retaining something of a round shape. Just lightly oil the dough ball, drop it into the bag, twist the open end into a pony tail as close to the dough ball as possible (the idea is to exclude air from the bag) and then tuck the pony tail under the dough ball as you place it into the fridge. Why a pony tail? A pony tail is not an air tight seal so it will allow the bag to both expel gas and expand as the dough expands without fear of the bag tearing. To remove the dough ball from the bag just roll/pull the top of the bag down over the dough as you invert the bag allowing the dough ball to invert the bag as it falls free onto a floured surface, if you're so inclined you can place the used Food Bags into a sandwich size Zip Lock bag and store in a corner of the fridge, they're reusable any number of times. If you want to save up a few bread bags you don't need to buy the Food Bags (they're cheap) or you can buy relatively inexpensive bread bags on the Internet and not have to worry about buying them again for a long time.

[Re: Making Neapolitan Pizza Dough - Rising and forming pizza](#) **2988**

Yep, I just mix it right into the water.

[Re: Best time to add starter in final mix](#) **2989**

To the best of my knowledge FB has nothing on me at all. Don't do ANY social media, never have, never will. Plenty of other sources most likely have a lot of stuff on me though.

[Re: Facebook knows everything about you, and it's scary!](#) **2990**

Made a 45-Kg. flour based pizza dough in Guyana, 65F off of the mixer, direct to the bench for scaling and balling, oiled dough balls, bagged dough balls, places on sheet pans in a rack in the walk-in cooler, came back to it on the following day only to discover that the dough had essentially liquefied over night (it came out of the bag looking more like a very thick cream than dough). That's where I learned my lesson about damaged starch and fermentation.....they don't play well together at all! Oops!

[Re: What was your worst pizza mistake.](#) **2991**

You will get a different crust if you bulk ferment as opposed to what you're presently doing. You will also, in all probability, introduce a new world of inconsistency to your customers which will not be good for business in the long run. My recommended solution: Purchase a free standing walk-in cooler and install it "out back" where you will have ready access to it. This is a very common fix to a very common problem.....and it works well.

[Re: Batch fermentation](#) **2992**

I always mix my sourdoughs the same as I mix any other pizza dough, just until it begins to take on a smooth appearance..no more than that is needed. You can do it by hand if so inclined, or by machine.

[Re: effects of mixing on sd pizza](#)**2993**

Q.J.:

Spot on! :) The use of oil in the dough can really have an impact upon the flavor of the crust as it will better enable it to retain flavors released from the pizza during the baking process.

[Re: Dough tastes boring - what to do?](#)**2994**

Peter;

Your assumption is a valid one but it doesn't take into account one very important enzyme contained within the yeast cells, that enzyme is invertase, its main job, if you want to call it that, is to break down (hydrolize) the disaccharide (two sugar) sucrose into its monosaccharide (single) component sugars (dextrose and fructose) which are then available for the yeast as a nutrient. The action of the invertase is nearly instantaneous as it occurs during the mixing of the dough. This is also the very same reason why the addition of sucrose aka table sugar (a non-reducing sugar) to the dough allows for the development of additional crust color during the baking process.

What you observed when making the emergency dough with 0.8% IDY is what I would have expected to see, at least from one on my emergency dough which is ready to be opened into a skin between 60 and 90-minutes after coming off of the mixer. The total life of one of my emergency doughs is something less than 3-hours on average so it's fermenting VERY FAST to say the least. By the way, my fastest emergency dough (made at the P.H. Headquarters in Dallas, TX) was just under an hour from scaling ingredients to the pizza coming out of the oven. The story behind the dough:

Mr. Lehmann, how fast can you make a pizza from dough to oven?

I'm not sure of the exact time but it would be around an hour.

Can you make enough dough for four pizzas?

Sure! Do you want me to show you how to do it?

Yes!

With that I scaled-up the dough and proceeded to mix it, scale the dough balls and ball, oiled the dough balls and covered with a sheet of plastic to ferment until the dough could be opened, in just under an hour after starting we were eating pizza. When I asked them why they wanted to see this they responded: Oh, it was getting close to lunch time and we didn't want to have to run over to the cafeteria for pizza.

Just goes to show you, emergency dough pizza really isn't all that bad....all things considered. :)

[Re: honey](#)**2995**

And we also need to look at your dough formulation, amount of yeast (we have to know the type of yeast you're using too) as well as the amount of salt you're adding to the dough formula are important considerations when assessing a dough formulation when flavor or lack of flavor is an issue. Lastly, do you weigh or portion your ingredients?

[Re: Dough tastes boring - what to do?](#)**2996**

Mike;

The reason why I asked is because if the total dough weight is under 1.5 Kg. (3.3-pounds) the dough will ferment the same if it is balled or in bulk due to the small size. I discussed this to some extent in an earlier post. The dough has to be sufficiently large to retain the heat generated through fermentation/yeast metabolism (heat of metabolism) to show the effects of bulk fermentation. However, if you allow the dough to ferment, whether it be in "bulk" or as dough balls prior to placement in the fridge for a cold fermentation period the dough will ferment prior to going into the fridge making it perform more like true bulk fermentation regardless of the dough weight. This is due to the change in dough density resulting from fermentation making the dough a better insulator and better capable of retaining heat while in the fridge.

[Re: Bulk cold ferment or ball then cold ferment?2997](#)

Steve;

There is a group of PMQ Think Tankers planning to meet on March 20th. following the Beer 'N Bull have you given any thought to possibly joining them? I'm sure they would be receptive to the idea. There is presently discussion on it on the PMQ Think Tank discussion board.

[Re: International Pizza Expo2998](#)

Mike;

Out of curiosity, what is your total finished dough weight?

[Re: Bulk cold ferment or ball then cold ferment?2999](#)

You got me on that one! :-D

All kidding aside, the little known fact is that the darkest grades of honey (also the lowest cost) are the one preferred for baking applications, not just due to their lower cost but mostly due to the fact that the flavor is more intense (robust) with the darkest honey grades. The least desirable for baking applications, if flavor is a reason for including honey in the formulation, is the grade referred to as "water white" this is the lightest colored grade of honey (also the most expensive) and from a baking perspective, has the most delicate (least intense) flavor of all the honey grades.

[Re: honey3000](#)

The 20" screens are available from just about any restaurant supplier (might need to special order) or American Metal Craft. I can't help you on a 30" as the largest I know of is 28".

Whatever you get just make sure the rims are either riveted or spot welded, NOT stapled. Most health departments take a dim view on the stapled ones as the staples come apart. You might check with Lloyd Pans to see if they are doing a 30-inch diameter aluminum screen.

[Re: Pizza screens3001](#)

Here are the reasons for adding honey to a pizza dough formula:

- 1) Nutrient for the yeast to feed upon.
- 2) Residual honey/sugar contributes to crust color through participation in the Maillard browning reaction.
- 3) Residual sugar can provide a sweet taste to the finished crust if used at a sufficiently high level to begin with.
- 4) Redeeming social value, it makes you feel better using honey than that nasty stuff we refer to as "sugar".

5) You don't mind spending \$9.00 a pound for honey when you can accomplish the same thing using regular sucrose for less than \$0.50 a pound.

[Re: honey](#)**3002**

Yael;

Post your question in the PMQ Think Tank too. There are several very good Canadian operators over there who I am sure will be glad to provide you with some first hand knowledge of what it takes to have a pizzeria in Canada.

<www.pmq.com>

[Re: Opening a pizza shop : USA vs CANADA](#)**3003**

How about the food processor you probably already have sitting on the kitchen counter?

[Re: Parmesan Grater for 2 to 3 lb at a time](#)**3004**

To achieve the characteristics you're looking for the first place to start is with the dough absorption, ramp it up to 70% and bench mark from there. With your slightly greater elevation you will get even more oven spring than at sea level to 1,500 feet above sea level (Naples). At what temperature are you baking at?

[Re: Neapolitan pizza in montana](#)**3005**

I've had my best success baking them at 500F in a deck oven or 465F in an air impingement oven.

[Re: Cracker Crust Issues](#)**3006**

Almabts;

How about just replacing the sun dried tomatoes called for with pieces of FRESH, VERY RIPE plum tomato? Cut the tomato into slices about 1/8-inch thick and then cut into quarters, use this rather than the sun dried counter part.

[Re: Sun-dried Tomatoes](#)**3007**

That would be a good place to start at, and then slowly increase the absorption in 2% increments until either you have too great a difficulty in handling the dough or it collapses during baking.

[Re: What would cause pizza to stay dense](#)**3008**

Sounds about right for a cracker style crust. Too stiff to open any other way except to use a rolling/pastry pin..right? If so it sounds to be "spot on".

[Re: Cracker Crust Issues](#)**3009**

My mother was German and my father was Italian and then there's me. I guess that explains why I like sour kraut and pizza.

My father died in the last months of WWII and my mother remarried hence my last name which is very German.

[Re: What are you made of](#)**3010**

Baking as you are I would expect that the absorption of your dough should be in the 70% range to give you optimum oven spring characteristics. Lower dough absorption values (high 50's to low 60's) are usually employed when baking at lower oven temperatures, say...in the 500F range. If the dough absorption is too low when baking at high temps the dough is too stiff/firm to give full expansion during the critical oven spring stage of baking where as the dough made with a higher absorption will be softer/more fluid and expand more readily during the oven

spring stage of baking.

[Re: What would cause pizza to stay dense?3011](#)

Jr07;

Do you mean extensibility?

Elasticity means that the dough keeps fighting you as you try to open it into a skin. If the dough was soft and extensible (easy to open) the fermentation was probably sufficient so that leave the oven to look at. What kind of oven are you using? What is the confirmed baking temperature? What are you baking your pizzas on? How long do you allow the oven to warm up before baking a pizza?

[Re: What would cause pizza to stay dense?3012](#)

Also, was the dough ball easy or somewhat difficult with a lot of dough memory/elasticity to contend with while opening the dough ball into a skin.

Assuming you're opening the dough ball by hand and using a fixed weight for each dough ball?

[Re: What would cause pizza to stay dense?3013](#)

In a word, yes. But at the same time I do realize that the type of wood being burned will have some impact upon the aroma of the pizza. A great example of this was when pine was being used to fire the oven, it resulted in a piney tasting and smelling pizza, sorta like sauce and cheese on a pine plank would best describe the flavor of that pizza. Cardboard resulted in another interesting flavor as the finished pizzas literally tasted like proverbial cardboard, not too much better for the paper which was whetted and rolled into a log shape, dried and used to fire the oven, not to mention all the ash on the pizza. The real "kicker" was the pizza baked in an oven fired by a kerosene heater (operates like a mini jet engine), those pizzas tasted just as if they had been baked over a diesel exhaust stack...yum! Come to think of it, there is one that I haven't had yet, pizza baked in an oven fired by cow chips/pies, I know they're burned as fuel but at least to the best of my knowledge, I haven't had a pizza baked in an oven fired by them yet and now that I've limited my International travel hopefully I've limited the possibility. That's what has made the International travel part of my career so interesting, you get to see just how resourceful people can be.

[Re: Coal fired pizza...give up the dream?3014](#)

If it burns or can be made to burn I've probably worked with an oven fired by it (coal/anthracite, hard wood, soft wood, fruit woods, paper rolled into logs, cardboard, kerosene, electric and all forms of gas). The type of pizza you are attempting to make will determine the temperature you operate your oven at. For example, a number of years ago I was working with a fellow in Dallas, TX on his pizza concept using a wood fired oven. The problem he was having was getting his pizzas crispy enough to satisfy his customer's demands. To do this we finally ended up operating the oven at 600F and baking for a longer time. Since his main business was DELCO he finally sold the wood fired oven and replaced it with a stone hearth gas fired oven.

In both New York City and South Carolina I worked with coal fired ovens and in both cases we were baking in excess of 900F with great results BUT the dough was entirely different AND both were dine-in pizzerias. I've worked with any number of wood fired ovens operating in this temperature range too with similar results when the application was correct (right dough and right audience). While a coal/anthracite fired oven might be able to achieve a higher operating temperature than wood I've yet to actually see that put into use in a commercial application.

By the way, when managing a coal/anthracite fired oven I've found it much easier if you have the coal put up into 5# bags. it's a lot easier to handle too.

From a commercial standpoint the only drawback to a single fuel source oven (wood or coal) is that you're locked into feeding the beast 24/7/365, to get around this I really like the idea of a dual fuel oven where the second fuel is gas. This allows you to idle the oven at 350F during the night and when the store isn't open and then get it back up to operating temperature within a reasonable time on the following day. There was a very practical aspect to the pizzeria and bakery owners living above their business establishments back in the early 1900's, their ovens were primarily all coal or wood fired which needed constant feeding and the trip down to the oven was a short one when you lived immediately above it.

[Re: Coal fired pizza...give up the dream?3015](#)

How are you mixing the dough? I see you are using 1-pound of flour, are you weighing out this amount? The other ingredients are all portions rather than weights, since we all portion differently there can be differences in portion weights. Do you have a scale that will weigh in grams? If so, can you provide the portion weights that you are using? You mention an issue with flavor, problems with flavor are normally associated with salt (not enough), fermentation (insufficient) and baking (insufficient). Can you share with us how you are managing your dough (this is everything you do to the dough from mixing to opening it into a pizza skin). Additionally, what is the finished dough temperature? You mention that the dough was still too tough to open even after 24-hours fermentation at room temperature. Did the room temperature fermented dough show much in terms of expansion of the dough ball after 24-hours? If not your issues might be due to;

- 1) Old yeast.
- 2) Incorrectly hydrated/activated ADY.
- 3) Excessive salt, but I really don't think that is the issue here as you would be detecting a salty taste in the finished crust.

How did the dough feel after mixing? Was it tougher/tighter than what you had with the KA flour? If it was the AT flour might just require more water than the KA flour. Flour is the most variable of all the basic ingredients used in making a yeast leavened dough.

Sorry to have more questions than answers but with more information I'm sure we can get you back on the pizza making track again.

[Re: Cracker Crust Issues3016](#)

Bill;

That seems to be the accepted way to go about it, put it right on the deck to achieve the oven spring and to set the structure, then transfer the crust to a screen to finish baking off of the deck so as not to get too much bottom color on the finished crust, in a way it like "having your pizza and eating it too", the best of both worlds.

[Re: 80% hydration pizza3017](#)

I haven't seen the article but he is absolutely correct about the high absorption doughs providing a crispier texture. I have said for MANY years that if you want to have a crispier crust characteristic increase the dough absorption, to a point. The increased absorption allows for faster expansion and more expansion of the dough during the critical oven spring stage of baking, this in turn allows for improved bake-out and a less dense structure which are the factors contributing to a crispier

characteristic, however you do need to have sufficient oven temperature to achieve maximum oven spring with these high absorption doughs but like everything else there is a limit to the temperature part of the equation, too hot and you get the oven spring but you don't get the baking time necessary to fully bake the dough/crust all the way through so you end up with a crispy crust fresh out of the oven but it quickly turns soft and limp with less than desirable eating properties. You can also go the other way with regard to absorption and reduce it down to something in the 30 to 40% range to make a thin crispy or thin cracker type of crust but now you have a crust that is different in that it is crispy pretty well all the way through.

When making high absorption doughs it is important to remember that the absorption level must be matched to the oven temperature, by this I mean if your oven will bake at 850 to 900F you will soon find that you can successfully use a higher absorption than you can if your oven will only reach 700F, in which case the definition of "high absorption" will have a lower number immediately before the "%" sign, you will still get many of the benefits, just not to as great a degree.

[Re: 80% hydration pizza](#)**3018**

We really need more information to address your questions, we need to know what type of yeast you're using and how much, we also need to know your entire dough formulation as well as the finished dough temperature (temperature after mixing). You mention that the dough is shiny coming off of the bread machine, this sounds as if the dough is being mixed too much for a pizza dough, you only want to mix the dough to a smooth, satiny appearance as this will give you the best finished crust characteristics.

[Re: NEW TO ALL THIS AND IN UK BUT WOULD APPRECIATE HELP PLEASE?](#)**3019**

Victor;

To address your questions;

#1) Flavor is OK after 24-hours, much better after 48 and quite good after 72-hours. The main reason why many pizzerias don't go to a 3-day dough is due to keeping track of the day the dough was made on and the need to have an inventory of 3-days of dough plus any carry over (4-day dough).

2) Don't sweat the humidity issue, instead concentrate on achieving a constant finished dough temperature. As for yeast level I have always used 0.375% IDY for a 48-hour dough with 1-day carry over and 0.4% for a 24-hour dough with 1-day carry over. If you've got the temperature control thing under control a lot of times you can eek out an extra day from the 24-hour dough allowing you to carry over any unused dough for up to two additional days, giving you a three day dough. This can only be accomplished using a walk-in cooler as I've never been able to effectively get that second extra day when using a reach-in cooler.

3) While it can be done, I'm not a big advocate of using a biga or starter in a commercial pizzeria setting as it is just another thing to go wrong and you really don't have much of a margin for things to go wrong in a pizzeria.

[Re: Fermentation and Temperature](#)**3020**

Actually, my first preference is to bake them on screens, then disks or cookie sheets as it is much easier to control the bottom bake color this way.

I bake mine at 430F.

[Re: Stromboli](#)**3021**

The reason why I asked is because HOT POCKETS is a registered trade marked

name that is jealously guarded, to about the same extent as Micky Mouse and other Disney characters are. "HOT POCKETS" are different from calzones.

[**Re: Hot Pocket3022**](#)

What Craig says is correct but when we bulk ferment the dough (large doughs is what I'm talking about here) the finished dough temperature is MUCH MORE CRITICAL than it is when the dough is subdivided, formed into balls and CF in that manner. Time and temperature are the two main drivers of fermentation so if the fermentation time is the same for two different doughs the dough that came off of the mixer at a higher temperature will ferment faster than the one that came off of the mixer at a lower temperature. No, bulk fermenting the dough in the cooler is not the solution as the dough is an excellent insulator and it continues to improve in this aspect as it continues to ferment so it is all but impossible to efficiently cool a large dough mass in the cooler, and to add insult to injury there is the heat of metabolism to contend with too, this is the heat generated by the yeast as it metabolizes nutrients during fermentation, this temperature gain is about 1F per hour. In some cases we see where a bulk fermented dough in the cooler results in a mottled finished crust color, which has been found to be due to the outer portion of the dough, that which was against the container, being cooler, thus conserving sugar and having a higher pH than dough from the center portion of the mass where there was little to no cooling of the dough resulting in more fermentation which allowed for greater metabolism of any sugar and the development of more acidity which inhibits crust color development. We saw a lot of this issue back in the late 60's and early 70's when pizzerias were transitioning from 100% room temperature bulk fermentation to a refrigerated dough management procedure. A good compromise that never really caught on was to form the just mixed dough into logs (weighing 6 to 8-pounds each) and 28-inches long (the length of an 18" X 26" sheet pan, two of these dough logs were placed on each pan which was then placed in the cooler (uncovered for 2-hours and then a plastic bag was slipped over the entire rack or over each pan of dough to prevent drying). The dough in this condition is really quite stable and can be held easily for two days and can even go as long as three days depending upon the finished dough temperature coming off of the mixer. To use this dough we just removed it from the cooler, allowed it to temper a little (just enough to be able to ball it), then cut each log into desired weight pieces, balled and placed back onto a lightly floured sheet pan, covered with plastic and allowed the dough to rest at room temperature until the dough could be easily opened into skins.

[**Re: Fermentation and Temperature3023**](#)

Hotpocket;

When you say hot pocket do you really mean "Hot Pockets" or do you mean calzones?

[**Re: Hot Pocket3024**](#)

Not too shabby! Here is an idea to help you win a few extra gold stars with her. For Mother's Day make another one just like that but make it in a heart shape. I've not made on in a ring shape, I've always made them in more of a bar shape....I think you're onto something there! ^^^

[**Re: Stromboli3025**](#)

Victor;

I would suggest the following:

Use a CF procedure for dough consistency and convenience, since you are flexible,

go with only a 1 or 2-day CF rather than a 3-day. This will reduce the number of boxes of dough by about 1/3. Depending upon dough weight/pizza size you should be able to get 8 dough balls per box, assuming 333 dough balls per day are needed (1000 divided by 3 = 333), 333 divided by 8 = 42 dough boxes will be needed for the dough ball inventory, this will be only 2 to 2+ a partial stack in your walk-in. Adjust the dough temperature off of the mixer to about 85F, follow my suggested dough management procedure and you should have a very good and consistent quality dough to work with. Additionally, using CF the addition of scrap dough back to fresh dough will not have as dramatic impact upon the overall quality of the dough (especially in view of the fact that you are considering as much as 20% scrap add back) as a room fermented dough would have. It will also be much easier to manage your dough ball inventory using CF as you will almost assuredly be able to use the dough balls one day beyond their CF period, meaning if you don't use a dough ball today you can still use it tomorrow.

If you use a RT management procedure you will need to pay special attention to managing the scrap return to your new doughs, it is highly recommended that you limit the scrap return for RT dough to not more than 15% of the new dough weight, so if you're making a dough based on 50-pounds of flour the total dough weight will be around 84-pounds which means the maximum recommended scrap return not exceed 12.6-pounds. Can you use more than this? Sure you can but dough quality as well as finished pizza quality will be impacted, remember GIGO.

As to the type of yeast that you use, any type CY, IDY or ADY will work just fine so long as it is USED CORRECTLY. My recommendation would be to use IDY for its ease of storage, long storage life, consistency and ease of use.

[Re: Fermentation and Temperature3026](#)

Winstonian;

Let me start off by quoting an age old adage: "A happy wife makes for a happy life". Of course you should make them for her! You have two choices when it comes to the dough, one is to use your regular pizza dough...it'll work just fine as long as the dough absorption is in the 58 to 62% range. The other option is to use a slightly richer dough for your strombolis to do this, going back to your regular pizza dough add 2 to 4% whole egg and replace the olive oil with unsalted butter or if your dough formula doesn't call for olive oil add 4% butter to the dough. While not traditional, this second dough formula really makes a great tasting stromboli. I like to finish mine off by brushing it with a little melted butter and then sprinkling it with shredded Parmesan cheese immediately before baking, or if you prefer, you can forego this step and brush it with melted butter as soon as it comes out of the oven and then sprinkle with an Italian herb blend and some powdered Parmesan cheese.

[Re: Stromboli3027](#)

The reason for twisting the open end into a pony tail and tucking it under the dough ball is just the opposite, it allows the bag to "self burp" thus releasing any gas accumulation and prevent the bag from being opened or burst by the excessive gas pressure. Following one of the laws of physics stating that cold air is heavier than warm air I would highly recommend packing the dough balls into the containers and then placing a piece of cardboard over the top layer and then add some dry ice on the top...8-ounces should be plenty for both cooler chests.

[Re: Pizza Party at park: Dough temperature-control3028](#)

Why not just oil the dough balls initially and drop them into individual plastic Food Bags, twist the open end into a pony tail and tuck it under the dough ball as you

place them onto aluminum sheet pans and place them into the walk-in cooler for the CF period, place 1/2 of the dough balls into a cooler (which has also been stored in the walk-in) for first use at the event, the second half would be placed into the freezer for super cooling (DO NOT FREEZE) about 20 to 30-minutes in the freezer will be sufficient, there will be packed into the other cooler for use later in the event. Being in plastic bag you can just arrange them in the coolers and remove at the event to warm in the bag, then just invert from the bag onto a floured surface and open. The bags would be discarded...fast, easy, and it works well.

[Re: Pizza Party at park: Dough temperature-control](#)**3029**

The level of fermentation that a dough has received is measured by both the pH and total titratable acidity of the dough. While being a by-product of fermentation the bubbles seen in the dough are not a good indicator of level of fermentation since they are greatly influenced by both the viscosity of the dough (softer doughs tend to promote larger bubbles while tighter/stiffer doughs tend to promote smaller bubbles additionally, as previously indicated, the size of the container, relative to the dough size, in which the dough is fermented will also influence the bubble formation. Commercial pizzerias control the spreading of the dough balls in two ways, the first is through temperature control, keeping the doughs within a very narrow targeted temperature range (usually in the 70 to 80F range) and managing the dough in such a manner so as to allow for rapid and efficient cooling of the dough balls once in the box. The second thing that is done is to adjust the dough absorption so as to control the amount of spread of the dough ball during the storage period, this is why we almost universally see the dough absorption used in pizzerias running about 60% (+/- 2%).

[Re: Same NY style dough recipe, different flour & different containers...new problem](#)**3030**

If you're planning to bulk ferment a large dough mass your greatest concern should be with regard to achieving a CONSISTENT finished dough temperature, then just keep the dough in a draft free area and it will maintain temperature and humidity all by itself. Just be sure to drape a sheet of plastic over the fermentation container to prevent drafts and possibly evaporate drying.

[Re: Fermentation Process](#)**3031**

One thing to keep in mind is that all sourdough starters do not provide the finished baked product with an actual sour/tart flavor, it all depends upon the type of micro-flora you have growing in the starter. We have used specific types of sourdough starters to make panettone which is a kind of Holiday fruit bread. Additionally, your sourdough starter may not have been strong enough or you didn't use enough for the strength it was at.

[Re: Why aren't low inoculation sourdoughs sour?](#)**3032**

Additionally, I didn't see any dusting flour in any of the pictures? Actually, the dough looks pretty good.

[Re: Sticky Dough - can't ball - The Pizza Bible](#)**3033**

I must have missed it, I didn't see anything in the video to suggest a "dough room", all I saw was an open kitchen concept...is that what you are referring to? Temperature and humidity (relative humidity) of Naples? On what day? I'd go with controlling the dough temperature and bulk fermenting at room temperature while controlling the room temperature seasonally in Denver, CO. The biggest difference between Denver and Naples is altitude which means that there is a greater

potential for a seasonal temperature change in Denver, and then there is the effect of altitude on evaporation of moisture from the dough (it wants to dry out faster at altitude (5200-feet) than at something closer to sea level 0 to 1500-feet). Just controlling the dough temperature to something around 80F and keeping it covered with a sheet of plastic will do fine for emulating the R.H. of Naples (about 80% R.H.) I mention this because 80% R.H. is the point where there is very little moisture evaporation from the surface of the dough...regardless of where you're at. It appears that they bulk ferment in a large container (like a food contact approved bin) probably for 12 or more hours, and then turn the dough out onto the bench for scaling and balling (in the video they are using a box scraper to cut the dough for scaling (wrong tool, they should be using a bench scraper aka bench knife...really isn't a knife at all) and the lady doing the rounding (balling) is doing it EXACTLY as I do it, even to the reverse pull at the end of the procedure. Hummm, I wonder if someone might have been watching one of my videos?

Just to make sure we're both on the same track, please clarify what you are calling the "dough room".

[Re: Fermentation Process 3034](#)

That's a fine looking pizza there! :) :)

[Re: Stretching issues and timing? 3035](#)

Lard is a fat in the family of "plastic" fats...sure go ahead and use it if you like! It works well and like many other fats it imparts a unique flavor to the finished product it's used in. It's interesting to note that people ALWAYS comment on how great REAL tortillas taste...soooo much better than the ones you buy at the store. "REAL" tortillas are made with REAL/non-deodorized, LARD which provides tortillas with a wonderful flavor. So why doesn't everyone use lard? Lard gets a bad consumer rap due to health concerns and for all practical purposes you can't sell much when you show lard on the label...that's just a fact of life here.

[Re: dough making questions 3036](#)

Norma;

What I said was that using just milk kefir and Dutched process cocoa may just create a situation where the alkalinity of the cocoa (pH 9.8) neutralizes the acidity of the milk kefir almost instantly leaving nothing to react later in the oven...hence the baking powder. When you're using the cocoa powder in a baked product I find very little benefit from using the more expensive cocoa powders. The flavor imparted comes from the amount of cocoa butter present as well as the pH. If those numbers are similar you won't find much difference in flavor in a baked product. When you have a baked product that is supposed to be chocolate but lacks the chocolate flavor it's almost always due to the pH being too low. Stop at a donut shop and buy a chocolate cake donut...upwards of 15% dark (Dutched process) cocoa and yet you don't have a pronounced chocolate flavor...why? pH is the answer. You can't mess with the pH of a cake donut without destroying the quality of the donut itself due to too much or too little fat absorption during the frying process. DO NOT CONFUSE THIS WITH THE CANDY MAKING PROCESS...that's a whole different story.

By the way, one of the things that I do when making my "double chocolate coconut nut cake" mentioned in a previous post, is to use semi-sweet chocolate morsels in the batter. The morsels melt late in the baking of the cake so the chocolate retains its integrity (unlike a chocolate syrup which would get incorporated as a part of the batter) so after baking there is sort of a matrix of melted chocolate throughout the entire cake giving it a VERY chocolate flavor and I might add a somewhat desirable

"gooey" texture. I'm not sure how this texture might come across in a pizza crust BUT if it were a crust that was used just for the foundation of a dessert pizza it might work. This is similar to how we make the chocolate croissant dough where there are "splotches" of melted chocolate distributed throughout the dough for flavor...a trip to your local Panera will get you a chocolate croissant to sample.

[Re: Chocolate Dough Pizza3037](#)

It would be interesting to experiment in this direction (you would be making a "chemically leavened" crust as opposed to a yeast leavened crust. You have to be in developing a leavening system, if you just use the cocoa for the alkali and milk kefir for the acid part you're liable to cancel out the pH of the cocoa and end up with something that more closely resembles natural cocoa. Why not just experiment with a chemically leavened crust to begin with? Use a single acting baking powder (CALUMET) and blend it into a small amount of Crisco to encapsulate it with the fat, then blend this into the remainder of the fat (be it oil or shortening) and proceed to make the dough. Things to remember:

For each % cocoa added you will need to add 1.5% additional water.

The dough will not ferment (no yeast).

The dough will not rise until it goes into the oven.

You will want to have a fairly soft and extensible dough coming off of the mixer which will allow it to rise due to oven spring.

I would suggest starting with 5% Calumet Baking Powder for starters and benchmark from there.

Procedure?

Mix; Scale; Ball; Refrigerate (for convenience); Remove from fridge, dress and bake. You MIGHT need to allow the dough to warm up a bit?

Alternative Procedure:

Mix; Scale; Ball; Box; Oil; Seal to prevent drying. The dough might be able to be held for quite some time (several hours) in this manner?

[Re: Chocolate Dough Pizza3038](#)

Norma;

The most flavorful cocoa is cocoa made by the Dutched Process, this is where the cocoa powder is treated with alkali (high pH) to develop the dark color and more pronounced flavor. Natural cocoa has a lower pH but little flavor and gave the dough a "muddy" appearance.

[Re: Chocolate Dough Pizza3039](#)

Agreed. In the wholesale baking industry we use the delayed salt addition mixing method to reduce total dough mixing time and yes....they even forget to add the salt occasionally :(so I can appreciate your concerns.

[Re: dough making questions3040](#)

Peter;

You're ABSOLUTELY AMAZING!!! :)

[Re: dough making questions3041](#)

Many times here, PMQ and P.T.

Both serve the same purpose, entrap flavors, lubricate the dough for improved extensibility, seal the cell structure for improved oven spring, provides tenderness in the finished crust and adds a dimension of "richness" to the finished crust.

Shortening TENDS to promote slightly better volume/height in thick crusts than oil. No significant difference in thin crusts.

[Re: dough making questions](#)3042

I can't tell you how much oil to use, you'll need to make dough with 2% and 4% (if those are the amounts you want to look at) and judge for yourself to see what works best for YOUR application. Regarding the oil/fat addition, since when a very short mixing time in 1st. speed is employed I DO NOT advocate using oil in your dough, instead use shortening and add it right along with the flour (no special handling or addition method) and continue mixing the dough just as you do. Oil will change the viscosity of the dough in a way similar to water but because it functions so very differently than water I do not recommend including it the dough absorption calculation BUT do be aware that it WILL make the dough feel softer as you either add or increase the oil and if this poses a problem in handling address it by reducing the dough absorption by an amount equal to the weight of oil added. Shortening DOES NOT do this so it is not necessary to make any changes to dough absorption regardless of the amount of shortening used.

NOTE: In some very specialized applications where high levels of shortening are added to the dough (I'm talking about levels of 10 to 25%) it may be necessary to mix the dough to "normal" (whatever that is for the dough in question) and then add the shortening and mix at low or medium speed for an additional 4 to 5-minutes to incorporate the shortening. This is a very common practice when making a high quality sweet dough (think cinnamon rolls) where the total fat content is typically in the 18 to 22% range. The reason for these practices with high shortening addition levels is due to the fact that the shortening (at these high levels) will coat the flour and thus interfere with both flour hydration and gluten development.

[Re: dough making questions](#)3043

We experimented with making chocolate croissant dough back in the heyday of croissants. They already add chocolate to croissant dough but it's in the form of chocolate pieces, we wanted to see if we could make a decent "chocolate" dough for making chocolate croissants. The problem we were having at the time was related to the flavor of the dough, it looked like chocolate but it sure didn't have a chocolate flavor. The reason for this is due to the pH of the dough. Chocolate/cocoa develops its flavor in an alkaline environment....dough pH is acid and it becomes more acid with fermentation. When we added soda to the dough to get the flavor we were looking for fermentation all but ceased (pH too high). Because of this we stopped working on the concept.

[Re: Chocolate Dough Pizza](#)3044

Use the delayed oil addition method of mixing. Put water in bowl first, then the salt (no need to stir) and then the flour with the IDY added on top of the flour, mix at low speed JUST until you don't see any dry flour in the bottom of the bowl (1.5 to 2-minutes), add the oil and continue mixing at low speed for another minute then finish mixing at medium speed.

[Re: dough making questions](#)3045

I can't argue with you on that one! "Even a bad pizza is better than no pizza at all". I have a saying that I coined many, many years ago, it goes like this: "I've never had a pizza that I couldn't learn to like" ^^^

[Re: Freezing whole pies](#)3046

I've done N.Y. style crusts with just sauce, then dress the sauced crusts and bake with relatively good success. When I've frozen fully dressed baked pizzas I never really like the texture of the toppings after the final reheating (too soft and mushy).

[Re: Freezing whole pies](#)**3047**

Thanks for catching that, I neglected to change the salt and IDY to bakers %...Oops!

Here are the correct percentages for the salt and IDY in bakers percent;

Salt: 0.286%

IDY/SAF: 1.13%

The salt is still much too low and the yeast as IDY is really quite high for making pizza crust unless it's for an emergency dough.

P.S.

I'll lick the egg off of my face in the morning for breakfast :-D

[Re: dough making questions](#)**3048**

MBLUE;

You gave your dough formula in "true %" as opposed to bakers percent which is the more common and to a great extent, correct way to look at a dough formulation.

Here is your formula in bakers %;

flour: 100%

Water: 59.94%

Salt: 0.18%

Yeast (IDY/SAF): 0.71%

Based on this my recommendations would be to increase the salt to 1.75 or 2% and probably cut the yeast level in half as this is a very high level for IDY. I'm betting that just increasing the salt level will do wonders for the flavor and consumer acceptance of your crusts. With very low salt levels like you have the flavor of the crust is typically described as being "starchy" and flat/tasteless.

[Re: dough making questions](#)**3049**

Peter;

I classify the Chicago thin crust as a thin crispy type of crust...and I might add that I use the term "crispy" quite loosely in this description as only the very edges (the corner edges of the round pizza, remember it is a party cut pizza) even come close to resembling anything very crispy...that's just the way it is. A good example of a thin cracker type crust can be seen at Incredible Pizza, the silly thing holds up fantastically well on their pizza buffets. Thin cracker crusts are also what P.H. "used" to have back in the 50's and 60's but then changed to a more traditional thin crispy type of crust sometime around 1968 or so.

[Re: crispy crust](#)**3050**

Which ever you use just be sure to use it correctly (both method of addition and amount used). ADY has to be suspended in 100F water (use a thermometer) and allowed to activate for about 10-minutes before addition to the remainder of the dough water, IDY, on the other hand, is used at a level about 20% less than ADY and it is typically added in its dry form directly to the flour. The one exception to this is when mixing the dough by hand, in that case the IDY is suspended in 95F water and allowed to activate for 10-minutes prior to addition to the remainder of the dough water.

Aside from that you can expect essentially the same results between IDY, ADY and

CY (compressed yeast) as Craig noted.

[**Re: what yeast for Neapolitan**](#)**3051**

Peter;

Oil is a tenderizer, with regard to a cracker style crust it makes for a more tender/flaky eating crust. Work that we did many years ago showed that 8 to 10% fat (preferably as shortening or any plastic fat) gave the overall best characteristics. I might also add that this closely corresponds to what is typically used in the production of premium saltine and club crackers which come in at around 8% fat. The reason why I don't recommend oil at those levels is due to the possibility of the oil soaking into the flour. If you really know what you're doing oil can be used but a plastic fat is a LOT easier to work with in this case, and if you are using a VERY SHORT mixing time (under 2-minutes) a plastic fat is mandatory as it is impossible to use oil in this specific application without it soaking into the flour...remember, we're dealing with only two minutes or less total mixing time. Those dough formulations which do not contain any oil are normally referred to as "thin crispy" while those made with oil or shortening are normally referred to as "thin cracker".

[**Re: crispy crust**](#)**3052**

TXCraig1;

Amen to that! Too many people buy into the "better ingredients make better pizza" philosophy, agreed, it's part of the equation but if you can't consistently make a decent pizza better ingredients aren't going to make your pizzas any better. I liken it to a pile of the best bricks in the world....in the hands of a skilled brick mason he can build a castle, in the hands of anyone else, you're likely to get a pile of the best bricks in the world stuck together with mortar.

[**Re: Best water for pizza style**](#)**3053**

These are the things that will come into play when trying to develop a crispier crust.

1) Enhance oven spring.

- a) Make sure you have sufficient yeast in the dough formulation.
- b) Optimize dough absorption.
- c) Sufficient fermentation for an extensible dough.

2) Oven temperature should be balanced to the dough formulation.

3) Bake the pizza long enough to develop a thicker crispy layer across the entire bottom of the pizza.

4) Minimize the use of browning agents in the dough as much as possible to allow for #3 above.

5) The higher the flour protein the greater the POTENTIAL for a crispier crust.

6) Ensure the dough formula is in proper balance.

7) Develop good time and temperature controls over the dough, without these you cannot have effective dough management and without effective dough management you will not have a consistently crispy crust.

Those are the high points of achieving a crispier crust.

[**Re: crispy crust**](#)**3054**

MBLUE:

We really need more information. Your dough management procedure is very sketchy and we don't have a clue as to what your dough formulation is. With your procedure I'm guessing that the yeast level might be very low...can you confirm

yeast level and type used? A low yeast level can result in a reduction of crispiness as well as set the stage for a potential gum line just below the sauce.

Any additional information you feel comfortable sharing will help us to answer your questions.

[Re: dough making questions](#)**3055**

MakingPizza;

You just bring it out of the fridge and set the containers on the bench/counter top or some other convenient location. Like Yael said, make a note of how long it takes the dough balls go get up to 60F and then you can just go with the time. One thing you might try is placing the dough balls into plastic Food Bags (not Ziplok). Form the dough into balls, oil the dough balls with any food grade oil and drop into individual plastic bags, to close the bags, twist the open end into a pony tail and tuck it under the dough ball as you place it into the fridge...that's all there's to it. When you're getting ready to use the dough just remove it from the fridge and set it on the counter top for 60-minutes. To remove the dough ball from the bag, roll the bag down close to the dough ball and invert the bag allowing the dough ball to fall free from the bag onto a floured surface, flour the dough ball and begin opening it into a skin for immediate dressing and baking. When done right, the bag automatically makes a nice round dough ball. This procedure has been discussed here a number of time if you would like to look back in the archives to see how others use this method.

[Re: My Attempt at New York Style](#)**3056**

Craig;

I think you're confusing dough quality and bread quality. The "hardness" of the water is well documented regarding its effect upon the dough. As for bread quality, I'm not aware of any real benefits to the finished bread quality resulting from the hardness of the water unless it is a peripheral benefit resulting from the improved dough handling properties had when using hard water. This does not mean that you cannot have a decent handling dough when soft or treated water is used, you certainly can, but when comparing like doughs made with hard and soft water research shows that those doughs made with soft water tend to carry about 2% less absorption and they also have a greater propensity for stickiness/tackiness than dough made with hard water. Some commercial bakeries have their mixer water (water that is used for making the doughs) piped directly from the building main without any further treatment while the rest of the water is further processed through a water conditioning/softening system. Calcium is a very effective dough improver, especially where stickiness and strength are potential issues, this is why literature states that you get stronger, better handling doughs with the addition of milk (dry milk solids) to the dough....it's the calcium in the milk. Calcium has always been an ingredient in mineral yeast food too (calcium sulfate, ammonium sulfate, potassium bromate) are the main ingredients. The ammonium sulfate is where MYF gets its name from as the ammonium sulfate breaks down releasing nitrogen as a food source for the yeast (actually it has little to no effect on the yeast) so when bromate fell from favor it didn't take too long for baking companies to figure out what the "real" active ingredient in MYF was....calcium sulfate. If the water in question has sufficient calcium content you don't see any further improvement from the addition of calcium sulfate or MYF for that matter. There is also an acid type mineral yeast food that also contains MCP (mono calcium phosphate) as the acid source. With this type of MYF the MCP serves an important role in helping to improve the rate of fermentation in applications where the water is slightly alkaline. We ran head long into that issue when the AIB moved from

Chicago to Manhattan, KS back in the mid-1970's. The water in Chicago was as hard as a rock (city is built on a lime stone structure/lots of stone quarries) and slightly acidic (helps to keep the calcium from building up in/on equipment) so we just used a plain bromated MYF, not because we had to but because that's what the baking industry was doing. Then we moved to Manhattan, KS and all of our dough fermentation times were WAY off...Huh??? A check of the water soon disclosed what the problem was....our water had a pH of 7.3 at the lowest and 7.7 was the highest we saw...Good Grief! We addressed the problem by changing over to an acid type MYF and increased the amount from 0.25% to 0.5%.

Note:

Chicago has since changed their water treatment as it is now all pre-softened before it goes into the delivery system and Manhattan, KS has addressed their alkaline water issue too as well as going with pre-softened water into their delivery system. The reason: Water treatment is cheaper than equipment failure, maintenance, and replacement.

[Re: Best water for pizza style 3057](#)

Let us know how that works for you.

[Re: Stretching issues and timing? 3058](#)

Did you place the dough containers in the fridge uncovered? Why did you turn the dough out of the fermentation containers and allow to set out for 2-hours? They are supposed to go into the fridge uncovered for at least 2-hours. If you lightly oil the containers before you put the dough into the containers all you need to do is to remove the dough (leaving it in the container(s) and allow to temper AT room temperature to about 60F, then invert the container allowing the dough to fall onto a floured surface, turn the dough over a couple of times to get it completely floured and you're ready to begin opening it into a skin. You might also try partially opening the dough using a rolling or pastry pin to about 2-inches of full diameter, then finish opening by bench stretching or your preferred method of hand opening. As you continue to get more proficient with your opening skills you will be able to wean yourself off of the rolling/pastry pin and open the dough entirely by hand.

[Re: Stretching issues and timing? 3059](#)

Norcoscia;

Yes, non-bromated mineral yeast food goes by two different names.

1) Non-bromated mineral yeast food.

2) Calcium sulfate. Actually, since bakeries stopped using bromated mineral yeast food most have just switched over to using calcium sulfate because it is the majority ingredient and most beneficial ingredient in any commercial yeast food. You can get calcium sulfate at any drug store or many garden centers (the stuff you get at the garden centers will not be approved for food use). It is so cheap that farmers apply it to their fields to break up clods of clay.

[Re: Best water for pizza style 3060](#)

For any yeast leavened products hard water is better than distilled, RO or softened water. This is primarily due to the calcium in hard water which has a strengthening effect upon the wheat proteins making for a stronger dough with less stickiness/tackiness. If you need to use any of the treated waters named above all you need to do is to add some calcium sulfate (0.25%) to the dough and you're good to go. I wrote an article in PMQ on this very topic some time ago if anyone wants to research it.

[Re: Best water for pizza style 3061](#)

Making Pizza:

There are two reasons why I suggest 55F (it can be as high as 60F) instead of "room temperature". 1) The dough is a little easier to handle at 55 to 60F than it is at room temperature. 2) Room temperature is a great unknown. There is no consistency to "room temperature" while 55 to 60F is a known entity and it's always the same. As an example, I've got a friend in Australia and for him "room temperature" is constantly flirting with 37.7C aka 100F. As for the temperature of your fridge, there is only one temperature range that is recommended: 36 to 40F.

[Re: My Attempt at New York Style3062](#)

Your pizza appears to be very light in color possibly due to the oven temperature being off (cooler than what the thermostat shows it to be) or not knowing your finished dough temperature (immediately after mixing) the dough could be getting too much fermentation for your baking temperature. Fermentation produces acids (among other things) which inhibit crust color development unless you can bake at high temperatures. You might include 2% sugar in your dough formula to see if this helps or reduce the amount of room temperature fermentation to an hour or less before balling the dough and putting it into the fridge. The crust also appears to have a lot of dusting flour on it so you might want to concentrate on minimizing the dusting flour when making future pizzas. By the way, for your method of dough management I would suggest a finished dough temperature in the 70 to 75F range. I'm also assuming that you're allowing the dough balls to warm up to at least 55F before opening them into pizza skins. You say you have your fridge temperature set at "level 5" but that really doesn't help us as you need to know the actual temperature in the fridge...this will have a significant bearing on the rate of fermentation taking place. By addressing these issues you might find the dough balls holding their shape better too, if not we can help you sort that out too.

[Re: My Attempt at New York Style3063](#)

Jizza23;

The problem in using a domestic yeast in a true sourdough starter is that a sourdough starter is a delicate blend of wild yeast strains and lactic acid forming bacteria. It is the proportions of these microbes in the starter that give the finished/baked product its unique flavor. It was said for many years that San Francisco sourdough bread couldn't be made outside of the Bay area as no one was ever successful at making breads with a true sourdough flavor east of California. We studied this and what we found was that in every case where flavor was an issue they added domestic yeast to the sourdough starter. This was done to speed up the final proofing of the breads, as you know, a true sourdough bread requires approximately 12-hours to proof after forming. Bakeries producing sourdough breads in California had this consideration built into their processing schedule but other bakeries didn't...they tried to incorporate sourdough bread into their regular production/processing schedule (hence the addition of yeast) and the unique flavor notes were lost. We found that the addition of the yeast completely upset the balance of micro-flora in the sourdough starter and within a short time the yeast became the dominant micro-flora as a result the starter was "lost". With that understanding, today, sourdough products are successfully made across the U.S. but only in bakeries designed for making/handling sourdough products. To a great extent sourdough products are made most successfully by smaller bakeries which can better accommodate the long proofing times required of sourdough products. By the way, much of what we see on the supermarket shelves today promoted in one way or another as "sourdough" on the label are not made from a true

sourdough but instead incorporate what is referred to as a "dry sour" which is a sourdough which has been matured and then dried and ground into a powder for addition to the dough as a flavoring compound or it might be made as you have described, from a blend of yeast and sourdough starter, but in either case the flavor is far from what many would describe as a "true sourdough" flavor. This is why so many people recognize a true sourdough flavor as something different....it is. But remember that all sourdough starters are not the same, the flavor can range from sweet to tart/acid and in some cases can be down right disgusting, it all depends upon what micro-flora you're culturing.

[Re: Hybrid Starter Levain/Direct](#)**3064**

QP;

Eliminate the malt powder from the dough formula and let me know how the dough performs for you. Excessive diastatic activity in the dough can result in an overly slack dough condition which could manifest itself as you have described. Also, what is your measured finished dough temperature? This can impact the dough both by itself and also the effect of the diastatic activity on the dough.

[Re: dough stretches really quickly?](#)**3065**

Yael is right, there are some "00" type domestic flours available at a much lower cost. You will need to try them to see if they meet your specific requirements for the way you are managing your dough.

[Re: Any substitute for caputo 00 Flour which is suitable for Neapolitan pizza](#)**3066**

Stiks;

IOf you e-mail me at <thedoughdoctor@hotmail.com> I can send you a copy of a distributor's price list.

[Re: Fresh Mozz Price](#)**3067**

Nick;

I can't answer that as the price of cheese is very fluid. Perhaps someone who is buying directly from a distributor will identify the brand as well as the current price that they are paying for it.

I will get you a local (for me) price for Grande shredded mozzarella.

[Re: buying mozzarella direct from manufacturers](#)**3068**

In its own way hand mixing probably does a better job of mixing a very high absorption dough than a spiral mixer, in this regard an ARTOFLEX type of mixer might work quite well for mixing those very high absorption doughs.

The way the agitator works with the very slack dough condition is why it takes so long to mix the dough. There is a spiral mixer design that might be better suited for a very slack dough condition, this is the one with a wide breaker bar (about 75mm wide) and it also has a plastic scraper to assist in pulling dough off of the bottom of the bowl. Like other mixer types, all spiral mixers are not designed the same.

[Re: Pizza pala/in teglia \(Sicilian style\): troubles with hydration & dough mixer](#)**3069**

There is a HUGE difference in the way the dough interacts with the agitator when using a spiral mixer as compared to a planetary type of mixer, this is especially true with the larger size spirals. It is this difference which enables the spiral mixer to handle tough pizza doughs so much better than their planetary cousins and it is also the reason why the longevity of a spiral mixer is so much better than that of a planetary mixer. Spiral design mixers are really not the best suited mixers for

making really high absorption doughs. just watch the mixing action between the two designs and you will see what I'm referring to.

[Re: Pizza pala/in teglia \(Sicilian style\): troubles with hydration & dough mixer](#)3070

Peter;

Oops! You caught me!!! ;D

You're right. I do recommend 50 to 55F for application in pizzerias but in home pizza making applications where all of the dough will be opened within a rather short window of time I like to go with 60F as a temperature suggestion but in actuality, because of all the variations in the way we make pizzas at home and all the different temperature definitions of "ambient" I like to say 60F minimum but let it go longer if necessary, then note the internal dough ball temperature and whatever it is now becomes YOUR specific temperature to allow the dough balls to temper to before opening.

[Re: The "Basic Dough Recipe" from the Dough Doctor](#)3071

Craig;

You're right! There is a difference between politically correct food and good tasting food. They're beginning to learn this in the school lunch programs too. If I wanted to eat politically correct (whatever that means) I would not be eating pizza and certainly not the double chocolate, coconut, nut cake that I made last night for dessert. I know what you mean about supporting the kids, we do the same. I've even helped them do pizza dinners for fund raisers too. One of them raised over \$800.00 for the local grade school.

[Re: Girl Scout Cookies - Worse than before?](#)3072

I'm not aware of where you might be able to source just gliadin (one of the two wheat proteins making up what we call "gluten"). You can easily source vital wheat gluten (many supermarkets carry it in their baking section) which can be easily added to any flour to increase the gluten forming protein content of the flour. When adding VWG, for each 1% VWG added to the flour you will be increasing the gluten forming protein content of that flour by 0.6%. For example, if you have a flour with 11% protein content and add 1% (based on the total flour weight) VWG to the flour, the protein content of that flour will now be effectively increased to 11.6%.

Remember, for each 1% VWG added YOU MUST also increase the dough absorption by an amount equal to twice the weight of VWG which you added. Different types of wheat flour can have different protein levels, some high (14+%) and some low (10% and less). It is a fairly common practice with home pizza makers to make a blend of different flours to make specific types of pizzas. Which flour would be best to blend with Caputo flour depends upon the type of Caputo flour you are using as well as the type of pizza you want to make and to some extent the dough management procedure you wish to employ in making your pizzas. Do you have a specific reason for wanting to use a Caputo flour? Do you have an oven hot enough to bake pizzas made using Caputo flour to make the dough? It takes an oven temperature of at least 700F (800 to 900F is better) to properly bake dough made with Caputo flour unless you add sugar or diastatic malt to the dough formula.

[Re: Gliadin](#)3073

Congratulations! That's a mighty fine looking pizza! :chef:

[Re: Differences between 00 flour and bread flour](#)3074

I've not done it nor seen it done in a commercial oven so I can't answer that.

[Re: Hey Tom. Sd448 question.3075](#)

You got it right!

[Re: The "Basic Dough Recipe" from the Dough Doctor3076](#)

To answer your question in one word...yes. The amount of toppings that can be applied before a pizza becomes soggy (swamp pizza) depends upon how you have prepared the toppings, the amounts added (you already know that), the type of oven the pizzas are being baked in as well as the baking time (longer baking time allows for more evaporation of moisture) and air movement/circulation helps with the evaporation (like a hair dryer). If you par-bake your crusts prior to dressing you can carry more of the wet toppings than you can if you build your pizza on a raw dough skin.

[Re: Soggy pizza.... weight or liquid content of toppings?3077](#)

After it comes out of the fridge it goes straight to the bench for opening into a skin. If you ball it again you will be waiting another 6-hours or more for the dough to relax sufficiently so it can be opened into a skin without the dough having all of the opening characteristics of a tennis ball.

[Re: The "Basic Dough Recipe" from the Dough Doctor3078](#)

If you plan on using the same size dough formula the answer is yes. Keep in mind that the two flours in question MAY NOT be directly interchangeable due to the potential differences in malting between the two flours which will affect the way the pizza bakes.

[Re: Differences between 00 flour and bread flour3079](#)

Yes you may. You can attach it here or in a P.M. or send it directly to me at <thedoughdoctor@hotmail.com>

[Re: Sourdough pizza dough3080](#)

It's a baking procedure where the pizza is baked on a screen to limit the bottom bake, when the top of the pizza is almost done the pizza is removed from the screen and placed right on the deck for 15 to 30-seconds to achieve the desired bottom bake characteristics. This is a very effective way to bake a more heavily loaded/dressed pizza in a deck oven where one would like to bake the pizza longer but in doing so the bottom of the pizza gets too dark. This is just the opposite of "doming" a pizza which is common in high temperature ovens where the bottom of the pizza gets done first so the pizza is raised on a peel into the dome of the oven, where the temperature can be as much as 1,000F, for just a few seconds to achieve the desired top color characteristics.

[Re: Hey Tom. Sd448 question.3081](#)

All things equal the addition of sugar or more sugar to the dough will result in both the top and bottom of the pizza developing more color. You might also try decking the pizzas, a lot of pizzerias do it.

[Re: Hey Tom. Sd448 question.3082](#)

Actually...a lot of research has been done with mixing dough under controlled atmosphere (vacuum) back when the Tweedy Dough Mixing process was being developed in the U.K. Fermentation doesn't do very well in a vacuum as bakers yeast is aerobic, plus the things that grow in an anaerobic environment are typically not very "consumer" friendly.

[Re: Same NY style dough recipe, different flour & different containers...new problem](#)**3083**

You have two options...see which one you like best.

- 1) Soak in olive oil several hours or overnight before use.
- 2) Take a small quantity of your sauce, heat it just to a simmer, add the sun dried tomatoes and stir in. Place in the cooler/fridge for several hours or over night before using.

You don't want to hydrate as that will dilute the flavor.

[Re: Sun-dried Tomatoes](#)**3084**

We did the work back in the late 60's and found that it retards the fermentation rate. It's not the pressurized aspect, it's the fact that the dough presses against the sides of the container thus impeding the release of the leavening gas. This is why I personally favor using plastic bags to cold ferment my dough in.

[Re: Same NY style dough recipe, different flour & different containers...new problem](#)**3085**

In one word.....EXCELLENT!

They provide a sweet flavor and a great texture.

[Re: Sun-dried Tomatoes](#)**3086**

Andy;

- 1) Move dough rack further away from the oven.
- 2) Create a heat/thermal block between the dough rack and the oven.
- 3) Use a refrigerated catering cabinet for storing your dough in.

Take yer' pick.

[Re: Starting my own Artisan/Neapolitan pizzeria](#)**3087**

Just going to take a guess on this one as I would need to actually see the two doughs made with the different flours to do any better at this time.

The larger diameter container allowed the dough to expand outward (dough will always try to expand outward as it is the path of least resistance) so much of the leavening gas was not seen as it was allowed to escape into the space within the container (dough only retains a small portion of the leavening gas, the rest passes through it into the surrounding atmosphere) This is why you didn't see the bubbles. BUT you never said you had any problems opening the dough so I'm guessing fermentation was still OK, and you said the flavor was still good, again an indication that fermentation was still good. Because there wasn't as much gas trapped within the dough cell structure (the smaller container will help to prevent it from escaping into the surrounding space because there is LESS surrounding space) there was less present IN the dough when you opened it into a skin. The open cell structure is well known to be partially responsible for the crispiness as well as the firmness of the finished/baked crust. A simple test would be to use one of the smaller containers to ferment the KASL flour based dough in and see how it compares to a control dough made in the SAME size container at the same time. This is why, in research, we use the mantra "Change only one thing at a time". When something changes it's a lot easier to get a handle on the reason for the change.

[Re: Same NY style dough recipe, different flour & different containers...new problem](#)**3088**

If you read any of my postings on dough mixing you'll know that I advocate mixing

the dough JUST until it takes on a smooth, satiny appearance...no more. It sounds like that's where you are at. Well done! :chef:

[Re: Dough Texture to shoot for](#)**3089**

If your yeast is IDY the amount is fine for taking the dough right from the fridge, allowing it to warm AT room temperature to about 60F dumping it out of the container onto a floured surface and immediately beginning to open the dough ball into a skin. Without actually seeing your dough formula and knowing the dough temperature after mixing this is based on a lot of assumptions.

Try it and let us know how it worked for you, I think you're be fine.

[Re: Pre-portioning before cold fermenting](#)**3090**

Yep, had a BP electric deck oven with both top and bottom temperature control. The top wasn't a specific temperature control, it was more like a top heat damper but it worked well to allow adjusting the top bake. Crown height aka oven height (distance from the deck to the top of the oven) can have a significant influence on the way an oven bakes. We always baked our pizzas in the BP deck oven at 500 to not more than 525F. We could never get a decent temperature balance when baking at a temperature higher than that.

[Re: Hey Tom. Sd448 question.](#)**3091**

Look at the used restaurant equipment market to see if you can find a Hobart A-120 or A-200 mixer with a reverse spiral dough arm. The A-120 should handle up to about 2-Kg. flour based doughs while the A-200 should handle up to about 3.5-Kg flour based doughs. There has been some discussion here on these mixers and I think just about anyone would jump at the chance to get their hands on one (space permitting). These mixers don't require an unusual amount of space on the counter top BUT they are NOT portable either. A lot of people put these mixers either in their garage or on a sturdy wheeled stand so it can be moved out of the way when not in use.

[Re: Standing Mixers in Australia](#)**3092**

It all depends upon your dough formulation, specifically the yeast level. I ALWAYS make my pizza dough in a way similar to what you have described. After the CF period, remove the dough balls from the fridge, allow to warm to 50 to 60F (NOT ROOM TEMPERATURE), turn the dough ball(s) out of the container onto a floured surface and open into a skin for dressing. Hopefully you oiled the container prior to putting the dough in it thus allowing the dough ball to be easily turned out of the container.

[Re: Pre-portioning before cold fermenting](#)**3093**

I realize that the amount of bake that a pizza received is purely a personal preference type of thing with mine being that the bottom of the pizza be baked a bit more than the top of the pizza, thus assuring a nice crispy pizza without excessive char on the top. With that said, too much bottom color:

- 1) Oven temperature too hot for the crown height of the oven.
- 2) Use of sugar (any type), eggs, milk or anything which would contribute to the browning reaction in an oven which is too hot for the dough formulation.
- 3) Burners too close to the deck or providing too much heat to the deck.
- 4) Deck material not sufficiently thick.

Any one of these might be responsible based on the information provided.

[Re: Hey Tom. Sd448 question.](#)**3094**

Define "pop-up pizzeria"?

[Re: What do you need for a Pop-up Pizzeria? 3095](#)

I know that P.H. contracts all of their cheese from Leprino and I've seen their trucks at various P.H. stores so I'm assuming if you're big enough there is a chance to buy directly from a cheese producer rather than a distributor. I can't speak to all of the large producers if they sell direct or not but there are many small and mid size producers from which one could probably buy direct. As for Grande, I don't THINK they do any direct sales unless it would be to one of the large frozen pizza manufacturers.

[Re: buying mozzarella direct from manufacturers 3096](#)

It sounds more like a leavening issue to me than a flour issue as flour will not have such a significant impact upon flavor (more subtle). I suggest trying more SD to see if that brings you back closer to where you used to be.

[Re: SD quandary 3097](#)

Alveograph:

A dough testing machine which measures the extensibility of dough by expanding a disc of dough with compressed air and recording the degree of extensibility of the dough before the bubble bursts. The Resultant graph gives an indication of the stability, the extensibility and the comparative strength of the gluten forming proteins in the flour being tested.

Farinograph:

An instrument used to measure development and certain other physical characteristics (tolerance to over mixing) of dough at a constant temperature. It also provides an absorption value for the flour.

Stability:

A measurement taken from the Farinograph curve as soon as the curve drops below the 500- B.U. (Brabender Unit) line on the chart. The stability value provides an indication of the tolerance of the flour to over mixing. The higher the number (in minutes) the more tolerance the flour has to over mixing. This is also a good indicator of the quality of the flour protein also. Higher quality protein = stronger doughs with all things equal.

Falling Number:

A laboratory device used to measure the level of alpha-amylase activity in the flour. The number provided by the Falling Number Test that indicates the level of diastatic activity in the flour. A falling number of 400 to 500 indicates a very low level of amylase activity while a number of 200 to 250 indicates a level typically associated with a malted flour (such as is typically used for bread and pizza production).

Dry Gluten:

The weight of the gluten after drying. In the U.S. we report gluten as protein content (nearly the same) but we typically report it on a standardized 14% moisture basis (this is the moisture basis that flour is sold on when purchasing in bulk). The gluten here appears to be reported at 10.5% moisture content resulting in a slightly higher protein/gluten percentage than if reported on a 14% moisture basis.

I know we have discussed this a number of times here at [Pizzamaking.com](#) so a quick search through the archives may shed a little more light on the topic.

[Re: measurements of rheological properties 3098](#)

That's the whole idea behind a sourdough culture. Once it matures, retaining the flavor. If the flavor changes from what it originally was it is due to a shift/change in the bacteria/wild yeast composition and the starter is said to have been "lost". Sourdough cultures, once developed, are rather difficult to maintain (they're like a long living pet....think a parrot) as they require constant and timely feeding as well as temperature control. Sourdough starters were not developed for the flavor that they developed in the finished product, instead they were developed as a means to leaven dough. It's only over the past 50-years or so that we have recognized sourdough starters for the unique flavor profile between different starters. I can still remember my grandmother going to the neighbors to get a small amount of their starter so she could make bread later in the week after finding that her own sourdough starter had "gone south" for whatever reason. I remember that she kept it in a 1-quart Mason jar on a kitchen shelf near the wood burning cook stove. From what I know now about sourdough starters today, the reason why she lost her starter was most likely due to lack of temperature control as it was stored too near to the stove where it was exposed to regular temperature fluctuations.

[**Re: SD starter vs. little yeast 3099**](#)

Additionally, you can also use frozen cheese (applied frozen) or you can find what is referred to as a low melt cheese, this is the type of cheese that is most commonly used in the commercial hot sandwich type products (avoided the commercial name).

[**Re: A question about cheese 3100**](#)

When I was at AIB another research group was doing a full blown research study on sourdough starters so I wasn't involved first hand but if I remember correctly the starters stabilized, in general, after about a month of culturing.

You can purchase a copy of the AIB Technical Bulletin on sourdough starters by Wulf Doerry by contacting the American Institute of Baking at

www.aibonline.org

[**Re: SD starter vs. little yeast 3101**](#)

Since you were NOT thoroughly cooling the dough prior to lidding the container(s) you ended up getting more fermentation than what the dough formulated for. You have two options (1) Further reduce the finished dough temperature. I seriously doubt that this will result in any significant change as 45-minutes unlidded cooling is just too short a time to allow for any real cooling to take place. So we go on to the next option (2) Reduce the yeast level in the dough to control the amount of fermentation the dough receives under YOUR SPECIFIC dough management procedure. Be aware that you should always be sure to allow the dough to warm to at least 60F (maybe more) before opening the dough when using low yeast levels. I suggest using your standard procedure with a reduction in yeast level, if you find the dough too elastic at the time of opening allow the dough ball to warm to a higher temperature the next time before opening as this will reduce the elasticity of the dough, continue making adjustments to the temperature of the dough ball before opening until the dough ball opens easily or to your liking. Use a stem type thermometer to measure the INTERNAL dough ball temperature prior to opening.

[**Re: Me again Tom...3102**](#)

A sourdough starter "is what it is", meaning that it doesn't change with age, a sourdough starter that is 1,000-years old and PROPERLY MAINTAINED will retain its original flavor profile. Does age make any difference in flavor profile? No. Every

starter lends a different flavor profile due to differences in the bacteria present so the trick is to find something that you like and then continue to culture or manage the starter so as not to change the bacteria profile in the starter (this is MUCH easier said than done).

[Re: SD starter vs. little yeast](#) **3103**

After I got off of the computer I thought I with all this talk about cake, why not make my wife her favorite treat? Yep, I made a double chocolate, coconut, nut cake. We had it for dessert after our Alfredo, shrimp and rice (Alfredo, fresh garlic, fresh basil and dried cherry tomatoes from our garden last year) this is all simmered and then dressed with a splash of lemon juice and served over rice. Fast, easy and good! Susan was ready to go straight to the dessert but she did manage to eat her dinner first. :)

[Re: Tom Lehmann's Sour Cream Cake Dessert](#) **3104**

Same for me too! :)

I also do a version using a chocolate cake mix modified in the same manner to which I add 1/2 cup of chocolate morsels, 1/2 cup of shredded coconut and I use chopped walnuts instead of pecans. We call it the double chocolate, coconut, nut cake.....This is my wife's favorite by a long shot! This one I like to serve with an icing (applied at the time of serving) using nothing but vanilla yogurt and then sprinkled with a little more coconut. :drool:

[Re: Re: Tom Lehmann's Sour Cream Cake Dessert](#) **3105**

If you don't have an orange handy at the time you can also use the zest from one lemon as a substitute for the orange zest. When I do this I like to toss in about 1/4-cup of shredded coconut. :chef:

[Re: Re: Tom Lehmann's Sour Cream Cake Dessert](#) **3106**

This is a little off topic but I thought I'd share it as it concerns my use of sour cream. When I do pizzas for the family occasionally I will make a cake for dessert. Being lazy I don't do scratch cakes very often anymore (except for pound cakes and fruit cakes). I use the box cake mixes, the ones where you only need to add oil, eggs and water. The yellow cake mix is preferred, what I do is to add an extra egg, reduce the water by 4-ounces, replace the oil with melted butter and include 4-ounces of sour cream, then blend together until smooth (a few lumps in the batter are OK), to spice things up a bit I add 1-tablespoon of vanilla, zest from one orange and 1/2-cup of chopped pecans, blend these into the batter and pour into an 9" X 13" greased (buttered and floured) cake pan and bake at 350F until the cake sets firm (use toothpick to test). These cakes are great just as they are without any added icing but you can ice them if you really have a sweet tooth. Right now I'm using the Pillsbury Traditional Yellow cake mix as I bought a bunch of them on sale over the winter for \$1.00 each.

[Re: Tom Lehmann's Sour Cream Cake Dessert](#) **3107**

Rolls;

You can probably get a copy at Amazon.

Don't forget to check out any used book stores too.

[Re: Differences between 00 flour and bread flour](#) **3108**

To me it sounds like a RECIPE FOR DISASTER!

Offer a few great pizzas as your mainstay, and then do "specials" these are NOT lower priced special, but instead they are different type of pizza that you might

offer once or twice a week (like a Tuesday and Thursday "special"). Now those specials become a "treat" and as everyone knows treats are better tasting than anything else! :chef:

[**Re: Selling nothing but pizza as USP 3109**](#)

Joe;

It sounds like you are not rounding the dough balls properly/consistent tightness which is what is causing the issue. Have you been to my web site <www.doughdoctor.com> and watched my videos on dough making? I discuss dough rounding in detail.

If you REALLY want to go the route of individual fermentation containers they will need to be oiled to ensure decent dough release (you don't want to have to dig the dough out) and yes, I HIGHLY recommend leaving the containers uncovered for 2.5-hours for a 20-ounce dough ball. My reason for not having a preference for individual dough ball containers in a retail setting is because they are a real pain to work with, especially when it comes to washing them (sorry, I have better things to do with my time than washing and drying all those containers and lids. Before going that route I might suggest using plastic food bags to store the dough balls in. Round the dough balls, oil them and drop into individual plastic bags (DO NOT USE ZIP-LOCK BAGS), twist the open end of the bag into a pony tail and tuck it under the bag as you place it on a sheet pan or other flat surface. By using this method you don't need to use the dough boxes and there is no cross-stacking required, just bag the dough balls, place in the cooler until ready to use (dough balls should have a 3-day shelf life in the cooler if you do your part). To use the bagged dough balls just remove from the cooler, allow to warm AT room temperature for about an hour (you may need to experiment to find the time that works best for you in your shop), pull the bag down around the dough ball and invert the dough ball/bag allowing the dough ball to fall onto a lightly floured surface. The bags can be reused a number of times IF they remain in a secure area (behind the counter). The dough balls DO NOT need to be perfectly round to be opened into a round pizza, if your people are having problems with opening the dough balls try using a rolling pin to open the dough balls to within an inch or two of the desired finished diameter and then finish opening the dough by hand. We developed this procedure a number of years ago as a training tool to help those who are challenged in opening dough balls. I've never seen a case where it didn't work wonders....no more thin center sections either! I have a video of this procedure being used in a commercial pizzeria if you are interested in seeing it just let me know.

[**Re: Me again Tom...3110**](#)

Alpha amylase aka liquefying amylase (naturally present in flour to a greater or lesser extent, also present in diastatic malt as well as amylase supplements, hydrolizes only the damaged starch into sugars. The native/intact starch granules are NOT hydrolized as they are the starch which develops the gel structure for making the finished product being bread, pizza crust, pastry, etc. without them the structure would not set during the baking process.

The amylase enzymes begin to denature at around 137F and complete activation is achieved at about 160F, this is the same temperature at which the native starch granules begin to gelatinize except the gelatinization process continues to a temperature of about 190F at which point all of the starch has been completely gelatinized. This is the reason why par-baked goods are ALWAYS baked to a minimum internal temperature of 190F though most go to 195F as an added level of assurance. If the starches are not fully gelatinized the finished product will either collapse during baking or cooling or at the very least it will have a wet,

gummy crumb structure.

The sugars formed as a result of the amylase hydrolyzing damaged starch are not just on the surface of the dough but instead are an integral part of the dough. It is only the residual sugars that participate in the browning reaction during baking as the other sugar has been metabolized by the yeast and is now in the form of carbon dioxide, alcohol, and acids (acetic, lactic and propionic) which is not sugar and does not participate in the browning reaction.

Keep in mind that the production of sugars by the amylase working on the starch will be limited by the amount of damaged starch present and crust color is not dependent upon JUST the sugars produced by the amylase. As the dough continues to ferment the yeast continues to produce acids (see above) these acids WILL significantly impact crust color development by reducing the crust color development, such as is the case with sourdough bread which will always have a very light crust color due to the acidity of the dough either formed naturally by the metabolism of nutrients by the yeast or added as an ingredient such as the addition of lactic acid to the dough to provide a sourdough like product. Additionally, crust color is an arbitrary thing, it is whatever you want it to be so many times we have to add something to the dough to improve the browning characteristics in order to achieve the DESIRED finished crust color characteristics.

If you want to learn more about bread making and everything related to it including fermentation and effect of different enzymes on the dough/bread I suggest getting a copy of Baking Science and Technology by E.J. Pyler. The book isn't cheap to buy but it's worth every cent if you want to learn the practical hows and whys of baking. If you have a nearby university that offers any kind of food or cereal science curriculum I'm betting that they will have this book in their library resource. Also check with your public library to see if they have it. The book is fondly referred to as "the Bible of the baking industry" and each of our Baking Science and Technology students at the American Institute of Baking had a copy.

[Re: Differences between 00 flour and bread flour](#) 3111

Yael;

To answer your first question, flour with less (to a point) damaged starch can indeed ferment slower but what concerns us more is that without added sugar to the dough the yeast can metabolize all of the available nutrient which then greatly SLOWS the rate of fermentation but more importantly, the yeast can begin to cannibalize itself releasing glutathione from the cells in doing so which will now cause the dough to become overly soft and sticky while exhibiting weakness. When there is an abundance of damaged starch the yeast doesn't ferment any faster as it can only feed on so much nutrient during fermentation (if you were to ADD an excessive amount of sugar to the dough it will most certainly slow the rate of fermentation. This is why when making yeast leavened pastries with high sugar levels we also significantly increase the yeast level at the same time (many pastries will contain upwards of 8 to 10% CY in their formulas when sugar levels are close to or above 20%. The one thing that higher levels of damaged starch does do is to provide a continual source of nutrient for the yeast to feed upon which is especially important when long dough fermentation times are employed. Like I said earlier though, the damaged starch absorbs A LOT of water in the dough making stage but when it is hydrolyzed it releases the water into the dough making for a wet, soupy dough after a couple hours of fermentation.

The Italian flours are milled from varieties of soft wheat which are much easier to mill to a low level of starch damage than hard red wheat varieties common to the U.S. and Canada as well as any other country importing wheat from either country and milling it themselves. As the differences in dough absorption, different

wheat varieties will exhibit vastly different absorption properties. In the U.S. and Canada the wheat varieties developed for use in milling into flour are bred for mixing tolerance, fermentation tolerance and absorption properties. They are looking for wheat varieties that exhibit slightly short to moderate mixing times, excellent tolerance to long fermentation times without breaking down, and high dough absorption characteristics (within reason). A good number of years ago (1968) there was a wheat-rye cross called Red River-68. The flour exhibited decent milling properties made good flour and had a reasonable mixing time as well as fermentation tolerance, so what was there not to like about it? The rye gene that was introduced into the wheat brought with it a unique property of rye flour.....STICKINESS. The doughs made with

Red River-68 were so sticky that you couldn't handle them! Remember, this is due to a genetic characteristic of rye so when we reduced the dough absorption all we got was a stiffer sticky dough that now exhibited a raft of other unwanted bread making properties. As you might have guessed, a lot of genetics goes into wheat breeding programs in many countries while in other countries the only concern they seem to have about the wheat is if it can be harvested and milled into flour. This is still true in most middle eastern countries there the order of the day is some type of flat bread which is typically made with not much more than an hour of total fermentation time.

[**Re: Differences between 00 flour and bread flour3112**](#)

Rob;

Nothing "chemical" about it. When dealing with white flour it is primarily the protein portion of the flour that carries the water/influences the dough absorption. When more water is added to the dough than what the flour is capable of absorbing the surplus water results in the characteristic stickiness due to dilution of the protein/gluten with water. There is a reason why it is called ("glue" ten) it is due to its inherent stickiness. Under normal circumstances the water is absorbed into the protein allowing it to be developed into gluten through the mechanical mixing action or through bio chemical gluten development which takes place during fermentation. Any water in excess of what can be absorbed into the protein just coats the protein on the outside which is what gives us the characteristic stickiness.

[**Re: Why is high hydration dough sticky?3113**](#)

If you are asking what is the best or preferred flour protein content for making Papa John's, Domino's and Chicago style pizzas from a commercial stand point the answer is a patent grade flour with a protein content between 12.8% and 13.2% for the big box stores and 13.8 to 14.2% for the Chicago style pizzerias.

[**Re: All Trumps flour vs. others for certain particular style pizzas3114**](#)

Yael;

May I ask, more specifically what are you trying to understand or accomplish?

[**Re: Differences between 00 flour and bread flour3115**](#)

Gary;

This topic was recently covered here in significant detail, check it out to see the entire discussion...short of it...break it down into smaller portions/bags and store in the freezer for longest shelf life and overall best results. If you don't have enough freezer space still break it down and store in the freezer for 45-days then remove and store at room temperature. Not the best but at least you will not have to worry about infestation in the flour as the freezing will kill any viable insect eggs that

might be in the flour. When storing at room temperature air tight is not the issue as it serves no benefit to the flour but you do want to protect the flour from infestation from outside of the bag so a metal or plastic container is recommended. Plastic 5-gallon buckets like you can get at a home center work great for this.

[Re: Storing Flour](#)**3116**

Jon;

It all has to do with temperature differential in the room. A great example of this is the differential between the top and bottom of the room where the floor or lower part of the room is cooler than the top of the room, and then there is the area near the door(s) where cooler air is introduced every time the door is opened, all of this leads to condensation.

By far, the best way to have controlled bulk fermentation is a small operation such as a pizzeria or small bread and bun bakery is to develop excellent dough temperature control measures and then bulk ferment in a suitably sized container (room temperature if fine) with nothing more than a sheet of plastic draped over the top of the container to retain the carbon dioxide which is heavier than air and creates an insulating (green house) effect over the surface of the dough. The purpose of the plastic in this case is just to keep that layer of carbon dioxide in place. If the sides of the container extend sufficiently above the top surface of the dough at full fermentation volume (about 18-inches is what is needed) you really don't even need the plastic IF the area is draft free. Why can you bulk ferment large doughs at room temperature? Because the truth is, the room temperature has little control over the fermentation of the dough, instead it is the temperature of the dough which has the greatest impact upon the rate of fermentation, this is why I said it is better to fine tune your skills at controlling finished dough/sponge temperature rather than wasting money investing in a "fermentation room".

[Re: Temperature Controlled Dough Room](#)**3117**

Additionally there appears as if there might be some anti-microbial properties to the wood work surface.

Wood/marble/ stainless steel that's also my order of preference too.

[Re: Bench: wood, marble, steel](#)**3118**

With conventional roller milling of wheat is is all but impossible to achieve a very high level of starch damage unless we're milling a soft wheat (better suited to cake and pastry production than bread and pizza) so the flour will have to go through some form of additional milling to get a high level of starch damage, this might include pin milling, ball milling or hammer milling (this is the way it is commonly done in Mexico and they use their Entilators (a type of hammer mill intended specifically for breaking insect eggs left in the flour post milling). The easiest way to achieve a higher level of starch damage is to simple add some pre-gelatinized wheat starch to any existing flour....PRESTO! Damaged starch content of the flour has just been increased. Remember...an increase in dough absorption due to an increase in the amount of damaged starch present in the flour is just temporary, after about an hour the damaged starch will be hydrolyzed into sugar and the water it was carrying will be released into the dough system resulting in a softer, stickier and more extensible dough, the magnitude of which will be dependent upon how much damaged starch was present. In many developing countries the amount of damaged starch is around 20 to 23% of the total starch present. 100-grams of flour is approximately: 11% protein, 12% moisture, and 3% ash and fiber. The remainder is carbohydrate/starch so, 100 minus 26 = 74-grams%. These are just very rough numbers for a typical white flour of around 76% extraction rate.
